Metastases

The vermiform appendix is the smallest and functionally most irrelevant segment of the gastrointestinal (GI) tract, yet diseases of the appendix are among the most common surgical emergencies in the western world.¹⁻⁵ The appendix arises from the posteromedial aspect of the cecum at the junction of the three taeniae coli. Although the appendix has the same mural layers as those of the remainder of the gut, it is distinguished by extremely rich lymphoid tissue in the mucosa and submucosa. This forms an entire layer of germinal follicles and lymphoid pulp in the young.⁶ With age, this lymphoid tissue underlying the mucosal epithelium and glands undergoes progressive atrophy. The distal portion of the appendix sometimes undergoes fibrous obliteration in older adults.⁶

Embryology

The vermiform appendix and cecum are intestinal derivations of the midgut. During the sixth week of gestational life, the cecum begins to develop as a small bulge in the midgut at the level of the ileocolic junction. This diverticular structure continues to enlarge and assumes a conical shape, with its apex corresponding to the primitive appendix.⁷⁻⁹ The initial cecal and appendiceal structures have been referred to as the "bud of the cecum."¹⁰ The midgut undergoes physiologic umbilical

herniation at approximately gestational week 6 and subsequently begins to relocate into the embryonal body cavity at approximately gestational week 10. This process is accompanied by counterclockwise rotation of the midgut, which results in positioning of the cecal complex in the right lower quadrant (Fig. 56-1). As the colon grows, it moves caudad toward the right iliac fossa, a process known as descensus.¹⁰ Because of differential growth rates during this time, the development of the primitive appendix is slower than that of the rest of the cecum. This differential growth was theorized by Broman to be caused by a mucosal fold in the distal cecum that prevents accumulation of meconium.¹¹ Broman hypothesized that colonic growth is stimulated by intraluminal meconium accumulation. Because this mucosal fold prevents complete filling of the distal cecum and appendix with meconium, growth is retarded in these segments. The appendix subsequently lengthens rapidly but fails to grow in thickness, soon assuming the configuration of a vermiform process.

By birth, the appendix has lengthened and shows a more abrupt transition zone at the junction with the cecum. At this time, the appendix is still attached to the cecal apex. The fully developed adult appendix is uniformly narrow and arises from the left posterior wall of the cecum, rather than the cecal apex, 2.5 to 3.5 cm below the ileocecal valve. The process of migration of the root of the appendix from the cecal tip toward the left, on the same side as the ileocecal valve, is probably related to the upright posture of the child. The right and ventral walls of the cecum grow and distend at the expense of the left and posterior walls. The fixation at the ileocecal junction and weight of the column of feces in the ascending colon explain this additional asymmetric development.

In adults, the root of the appendix can be located anywhere along the medial-posterior wall of the cecum, between the ileocecal valve and the cecal tip. In addition, there is great variation in the position of the appendix in relation to the cecum and ascending colon.^{12,13} More than 60% of appendices are retrocecal or retrocolic, with the remainder in a more inferior pelvic location. A fully developed appendix varies in size and thickness, with an average length of 8 to 10 cm (range, 4-25 cm; Fig. 56-2). The location of the appendix in the peritoneal cavity depends on its length and relationship to the cecum and the extreme variations in the mobility and location of the ascending colon and cecum (Fig. 56-3).¹⁴

Examples of arrest in later phases of development of the appendix are common and can be recognized during barium enema examinations. An arrest in the fetal phase of development is unusual (Fig. 56-4). A conic configuration of the lower cecal segment signifies total absence or hypoplasia of the appendix. Agenesis of the appendix is rare; the reported incidence is about 1 in 100,000 individuals.¹⁵

The ileocolic artery, a branch of the superior mesenteric artery, supplies the appendix, cecum, and ileum via five branches: (1) several ileal rami; (2) anterior cecal artery;

Figure 56-1 Embryology of the appendix. **A.** Growth of the inferior tip of the cecum lags during early intrauterine development. **B.** This produces the infantile appendix. **C.** Continued differential growth of the lateral cecal wall leads to the posteromedial position of the appendix in older children and adults. (From McVay CB: *Anson & McVay Surgical Anatomy*, 6th ed. Philadelphia, WB Saunders, 1984.)

Figure 56-2 Normal appendix: barium enema findings. A long pelvic appendix is present, arising from the medial wall of the cecum (c) below the ileocecal valve (open arrow). The appendix is uniformly narrow and completely filled with barium to the distal tip (solid arrows). This finding rules out appendicitis.

(3) posterior cecal artery; (4) colic ramus; and (5) appendicular artery, which runs through the mesenteriolum to supply the vermiform appendix. Because there are no arterial arcades in the mesenteriolum, the appendicular artery is a terminal artery, predisposing the appendix to ischemia when there is vascular insult.¹⁰ The appendicular artery origin is variable, with the following frequencies: iliac ramus (35%), ileocolic artery (28%), anterior cecal artery (20%), posterior cecal artery (12%), ileocecal artery (3%), and ascending colon ramus (2%).¹⁶ The veins accompany the arteries.

Lymphatic tissue begins to develop in the appendix during the 14th and 15th weeks of gestation.¹⁷ Initial accumulations of lymphatic cells occur directly below the epithelium, but some lymphocytes eventually penetrate the epithelial layer of the appendix. Lymphatic drainage of the appendix is via ileocolic lymph nodes located along the superior mesenteric artery and via celiac nodes into the cisterna chyli.

Unlike the cecal wall, which is composed of a diagonal rhomboid mesh of collagen fibers and allows it to accommodate luminal expansion, the appendiceal wall is composed of horizontal collagen fibers that tolerate only minimal increases in luminal diameter. Although the appendix secretes 2 to 3 mL of mucus daily, its average luminal capacity is only approximately 1 mL.¹⁰ This, in conjunction with the appendix's solitary blood supply, explains its propensity to become ischemic rapidly and perforate after luminal obstruction.

Acute Appendicitis

EPIDEMIOLOGY

Appendicitis was first described and reported by Reginald H. Fitz at the 1886 meeting of the Association of American Physicians.¹⁸ Appendicitis is the most frequent cause of acute abdominal pain requiring surgical intervention in the western world and is the most common abdominal operation performed annually in the United States on an emergency basis.^{19,20}

Appendicitis is rare in infants but becomes increasingly common in childhood. The highest incidence of appendicitis is in individuals aged 10 to 19 years (15.3/10,000 population/year).²¹ Across all age groups, the annual rate is approximately 9.4/10,000.²¹ The lifetime cumulative incidence is approximately 9%.²² There is a slight male predominance, with a ratio of 1.3:1. Mortality and morbidity rates for removal of a normal appendix are 0.14% and 4.6%, respectively, but increase to 0.24% and 6.1% for acute appendicitis and to 1.7% and 19% for perforated appendicitis, respectively.²³ These mortality rates are far better than the 50% mortality seen in the preantibiotic era.¹⁻⁵

Appendiceal perforation occurs in 16% to 39% of patients with a median reported incidence of 20%.²⁴⁻³¹ Risk factors for perforation include very young or old age, Asian or Hispanic

Figure 56-3 Variations in position of the appendix. **A.** Incidence of various positions of the appendix. **B.** Normal variations in the position and peritoneal fixation of the appendix: (a) intraperitoneal, pointing over the brim of the pelvis; (b) intraperitoneal, ascending retrocecal; (c) extraperitoneal, ascending retrocecal, with a paracecal fossa present; (d) extraperitoneal, ascending retrocecal; (e) extraperitoneal, ascending retrocecal, lying anterior to the right kidney (K) deep to the liver, associated with an undescended subhepatic cecum. (The terminal ileum is also extraperitoneal and enters the cecum from behind.) (**A** from Meyers MA: *Dynamic Radiology of the Abdomen*. New York, Springer-Verlag, 1988, p 403; **B** from Meyers MA, Oliphant M: *Ascending retrocecal appendicitis*. *Radiology* 110:295–299, 1974.)

ethnicity, and lower socioeconomic status.^{22,32,33} Although some early studies found a linear correlation between perforation rates and diagnostic accuracy, more recent studies have cast doubt on any relationship.^{28,30} A study of 1486 appendectomy cases found an overall perforation rate of 19%, with higher rates in the very young and older adults.²⁸ Vorhes noted that patients older than 55 years underwent laparotomy on average 2 days later than those younger than 55 years.³⁴ A large retrospective study of children (≤ 18 years) showed that the rate of appendiceal perforation was markedly higher for children younger than 5 years old (71.9% vs. 21.7% for children > 5 years) and that the risk for perforation was inversely proportional to the patient's age.³³

Acute appendicitis is the most common nonobstetric surgical emergency in pregnant patients, occurring in approximately

Figure 56-4 Fetal appendix. Barium enema examination in a 21-year-old woman shows arrest in the development of the appendix (A). The cecum (C) has a triangular, funnel-shaped inferior segment (arrows), with gradual transition into an incompletely developed appendix.

1 in 766 pregnancies.³⁵ Complications include premature labor and fetal and maternal death, especially when perforation occurs.³⁶ The fetal loss rate for nonruptured appendicitis is approximately 2%, compared with more than 30% in patients with ruptured appendicitis.³⁷

CAUSES

Acute appendicitis occurs after luminal obstruction. Causes of obstruction include fecalith, lymphoid hyperplasia, primary tumor (e.g., carcinoid, adenocarcinoma, lymphoma, Kaposi's sarcoma) or metastasis, parasitic infection, foreign body, stricture, Crohn's disease, and adhesion (Fig. 56-5). Prolonged retention of barium is no longer considered a risk factor for acute appendicitis.^{38–41}

Of the possible causes of luminal obstruction, fecaliths are the most common, occurring in 11% to 52% of patients with acute appendicitis.^{42,43} Fecalith formation results from inspissation of fecal material and inorganic salts within the appendiceal lumen. As they enlarge, these concretions can obstruct the appendix. Low-fiber diets contribute to low-residue stool, which has a propensity to become impacted in the appendiceal lumen. True appendiceal calculi (hard, noncrushable calcified stones) are less common than fecaliths but, when present, they

Figure 56-5 Pathophysiologic pathways in untreated appendicitis. (From Puylaert JBCM: *Ultrasound of Appendicitis*. Berlin, Springer-Verlag, 1990, p 5.)

have a higher association with appendiceal perforation and periappendiceal abscess formation.⁴³

Hygiene improvements of the modern world have greatly reduced the exposure of infants and children to enteric organisms. Consequently, when infections do occur, they can elicit an exaggerated lymphoid hyperplasia that may block the appendix or devitalize the appendiceal mucosa, allowing bacterial invasion.³⁸⁻⁴¹

PATHOPHYSIOLOGY

Continued secretion of mucus into the appendix after luminal obstruction results in distention and concurrent elevation of luminal pressures. When the luminal pressure exceeds the capillary perfusion pressure, lymphatic and venous drainage are impaired and arterial compromise and tissue ischemia result. Breakdown of the epithelial mucosal barrier occurs, and luminal bacteria multiply and invade the appendiceal wall, causing transmural inflammation and gangrenous appendicitis (Fig. 56-6). Continued tissue ischemia can result in appendiceal infarction and perforation. Perforation can cause a localized or generalized peritonitis as inflammation extends through the serosa to the parietal peritoneum and adjacent organs (cecum, terminal ileum, pelvic viscera). Although periappendiceal abscess or phlegmon is usually walled off by the adjacent greater omentum or small bowel, some cases will spread through the peritoneum to the paracolic gutters and subphrenic spaces, sigmoid colon, bladder, ovaries, or vagina. Infected thrombus may form in the portal vein, causing pylephlebitis, although this is unusual with modern antibiotics.^{1-5,44}

CLINICAL AND RADIOLOGIC ASSESSMENT

Clinical assessment remains an essential and critical part of the initial evaluation of patients with suspected acute appendicitis. The physician's goal is to confirm or exclude the diagnosis of acute appendicitis expeditiously while minimizing diagnostic delays, negative appendectomy (i.e., surgery for suspected appendicitis yields a normal appendix) and appendiceal perforation rates, and hospital costs. More recently, reducing or

eliminating ionizing radiation dose to the patient has become a major consideration driving the diagnostic approach, particularly in children and pregnant women.⁴⁵⁻⁴⁷ However, despite continued advances in clinical medicine, the diagnosis of acute appendicitis can sometimes remain elusive.⁴⁸⁻⁵¹

Although diagnostic accuracy rates for appendicitis in the United States had improved from 86% to 92% in male patients and from 74% to 83% in female patients between 1970 and 1984,^{14,20} one study suggested that imaging has helped improve accuracy. Perforation and false-negative appendectomy rates have stabilized in recent decades.²⁷ Cases of "missed appendicitis" typically reflect the frequent diagnostic difficulty of differentiating appendicitis from other causes of abdominal pain.^{52,53}

Historically, negative appendectomy rates of as high as 15% to 23% had been acceptable, with rates as high as 45% in patients with an atypical presentation or in women of childbearing age.⁵⁴ Negative laparotomy rates of 10% to 15% have now been considered acceptable, although that number continues to trend downward as imaging improves. Negative laparotomy rates remain higher in women of childbearing age.^{22,55} Diagnostic accuracy can be improved with inpatient observation, subsequently leading to a decreased negative appendectomy rate without a concurrent increase in appendiceal perforation rates.⁵⁶

A large retrospective study found that risk factors for negative appendectomy included very young or advanced age, female gender, and presence of comorbid illness. In that study, the highest rate of negative appendectomy was in women older than 70 years.⁵⁷ Negative appendectomy (compared with positive appendectomy) was associated with a significantly longer length of stay (5.8 vs. 3.6 days), case-fatality rate (1.5% vs. 0.2%), and infectious complication rate (2.6% vs. 1.8%).⁵⁸

Radiologic imaging has become an important adjunct to clinical evaluation. Accurate identification of an inflamed or normal appendix can greatly facilitate appropriate treatment. Imaging can also identify alternate diagnoses in patients with clinically suspected acute appendicitis.^{45,54,55,59-61}

Despite advances in radiologic imaging, controversy still exists in the literature about whether the increased availability

Figure 56-6 Pathology of appendicitis. **A.** The lumen fills with purulent exudate (hematoxylin-eosin, $\times 150$). **B.** Necrosis of the muscularis propria (solid arrows) and inflammation of the periappendiceal fat (open arrows) are seen (hematoxylin-eosin, $\times 80$). **C.** Transmural and periappendiceal inflammation and fibrosis are present with focal destruction (arrows) of the appendiceal wall (hematoxylin-eosin, $\times 6$).

of imaging and laparoscopy has decreased misdiagnoses and negative laparotomy rates. For example, Flum and associates performed a retrospective study of 63,707 appendectomy patients from 1987 to 1998.⁵⁷ They found that, contrary to expectation, the use of computed tomography (CT), ultrasonography (US), and laparoscopy did not change the negative appendectomy or appendiceal perforation rates.

In contrast, many subsequent reports have described reductions in the negative appendectomy rate associated with increased use of imaging. Jones and co-workers found a decrease in the negative appendectomy rate (from 17%-2%) coinciding with increased CT use from 2000 to 2002.⁶² The rate of appendiceal perforation also decreased (from 25%-9%) during the same interval. Rao and colleagues found reductions in the negative appendectomy rate (from 20%-7%) and perforation rate (from 22%-14%) with increased use of CT.⁶³ At Duke University, a 10-year retrospective study published in 2010 found that an increase in preoperative CT use from 18.5% to 93.2% resulted in a reduction of the negative appendectomy rate among 18- to 45-year-old women from 42.9% to 7.1%.⁶⁴ A study by Bendeck and associates showed a lower negative appendectomy rate for women who underwent preoperative CT or US imaging compared with women without preoperative imaging (7% vs. 28%, respectively).⁶²

In a large study of almost 20,000 patients, Drake and co-workers found a negative appendectomy rate of 4.5% in patients who underwent imaging versus 15.4% in patients with only clinical assessment.⁶⁵ Despite imaging, the negative appendectomy remained higher for women compared with men (6.9% vs. 3%).⁶⁶

FINDINGS

Clinical Findings

Most patients with acute appendicitis present with abdominal pain, although the classic presentation sequence of poorly localized periumbilical pain followed by nausea and vomiting and later migration of the pain to the right lower quadrant occurs in only half to two thirds of all patients.⁶⁷ The location of abdominal pain varies and depends on both the position of the inflamed appendix and stage of appendiceal inflammation. With initial distention and increased intraluminal pressure in the obstructed appendix, patients typically perceive visceral epigastric or periumbilical pain. During this time, the disease is usually confined to the appendix. When the inflamed serosa of the progressively inflamed appendix comes into contact with the parietal peritoneum, somatic pain is perceived, with the classic description of pain that shifts to the right lower quadrant.⁶⁸ In patients with a retrocecal appendix, the pain may be referred to the right flank, costovertebral angle or, in males, the right testis. Patients with a pelvic or retroileal appendix may experience pain in the pelvis, rectum, adnexa or, less commonly, left lower quadrant.⁶⁷ Nausea, vomiting, and anorexia are variably present, occurring in more than 50% of all cases.^{31,69}

Signs and symptoms vary with the inflammatory stage of the appendicitis. Abdominal tenderness is the most common physical finding, occurring in more than 95% of patients.⁶⁷ Although the classic teaching is that patients with appendicitis present with localized tenderness at or near McBurney's point (positioned 1.5 cm superior and medial to the anterior superior iliac spine and parallel to a plane drawn from the anterior superior iliac spine to the umbilicus), the point of tenderness will vary, depending on the position of the inflamed appendix. In one series of 275 double-contrast barium enemas, the appendiceal location was within 5 cm of McBurney's point in only 35% of patients and was farther than 10 cm in 15% of cases.⁷⁰ Usually, the appendix is located inferior and medial to McBurney's point.^{70,71} Patients may also present with Rovsing's sign (pain referred to the area of maximal tenderness during palpation or

percussion of the left lower quadrant), positive psoas sign (right lower quadrant pain with extension of the right hip), or obturator sign (right lower quadrant pain with flexion and internal rotation of the right hip). Voluntary muscle guarding in the right lower quadrant is common and typically precedes localized rebound tenderness. Bowel sounds vary but are usually diminished or absent with advanced appendiceal inflammation or perforation.⁶⁷

Most patients with acute appendicitis (70%-90%) present with a white blood cell (WBC) count greater than 10,000/mL and neutrophilia more than 75%.⁷²⁻⁷⁴ Serial WBC counts may be helpful in the diagnosis because it has been shown that patients tend to have an increased WBC count 4 to 8 hours after admission unless the appendix is perforated, in which case the WBC count typically decreases.⁷⁵ Because a minority of patients with acute appendicitis have a normal WBC count, a normal value is not sufficient to exclude the diagnosis.⁷⁶

Urinalysis is positive in 19% to 40% of patients with appendicitis; abnormalities include bacteriuria, mild pyuria, and hematuria.^{77,78} Abnormal urinalysis results are more commonly observed in women with appendicitis than in men.

Elevation of the C-reactive protein (CRP) level more than 0.8 mg/dL has sensitivities of 46% to 75% and specificities of 56% to 82% in acute appendicitis, and elevation is more common when symptoms are present for more than 12 hours.^{75,78-81} The diagnostic sensitivity for acute appendicitis is improved to 97% to 100% when an elevated CRP level, elevated WBC count, and neutrophilia more than 75% are all present.⁸¹

Imaging Findings

Plain Radiographs. The most specific plain film sign is the presence of an appendicolith (Fig. 56-7). However, appendicoliths are only found by radiographs in 10% of patients with acute appendicitis. When present on radiographs, the reported incidence of perforation is almost 50%. Appendicoliths are usually 0.5 to 2 cm in diameter and have a round or oval configuration and laminated rim. The calcified rim assists in differentiating them from bone islands, ureteral stones, and phleboliths. They may be obscured by the bone structures of the pelvis or may be ectopically located in the right upper abdomen in cases of retrocolic appendicitis. Appendicoliths are usually solitary, but two or three adjacent small calcifications are not unusual. Appendicoliths may be detected in asymptomatic individuals and, without associated clinical findings, are not indicative of appendicitis.⁸²⁻⁸⁵

Air in the appendix, particularly in the retrocecal location, is a normal finding. Extraluminal bubbles of air associated with an ill-defined soft tissue mass indicate an abscess (Fig. 56-8). Sometimes, the inflammatory process in the right lower quadrant induces a severe localized ileus, with dilation and air-fluid levels in the ileal loops and cecum. When severe, this process can mimic the appearance of a mechanical distal small bowel obstruction (Fig. 56-9). Dilation of the transverse colon in association with a gasless cecum and ascending colon may result from ileus of the transverse colon and spasm of the ascending colon. Free air in the peritoneal cavity is rare because the base of the appendix is usually occluded when perforation occurs.⁸⁶⁻⁸⁹

Other findings such as partial loss of the right psoas shadow and a lumbar scoliosis concave to the right are common, albeit nonspecific.⁸²⁻⁸⁵ Appendicitis may also cause a distal small bowel obstruction, particularly when perforated.

Figure 56-7 Appendicoliths. Two appendicoliths (arrows) are present in the right upper quadrant. The patient had a long retrocolic subhepatic appendix with acute appendicitis.

Plain film radiography is typically inadequate for the diagnosis of appendicitis. Ahn and colleagues retrospectively reviewed the records of 871 adult patients with nontraumatic acute abdominal pain and found that plain radiographs were normal in 23%, nonspecific in 68%, and abnormal in only 10%. The diagnostic sensitivity for appendicitis, pyelonephritis, pancreatitis, and diverticulitis was 0% in the study.⁹⁰

Barium Enema. Before the 1980s, the barium enema was the primary radiologic test used in the diagnosis of appendicitis. This examination can be performed quickly and safely with the single-column technique. Because appendicitis results from luminal obstruction, complete filling of a normal appendix effectively excludes the diagnosis (Fig. 56-10A). Nonfilling or incomplete filling of the appendix in the presence of mass effect (on the caput cecum and adjacent distal ileum indicates inflammation Fig. 56-11; Fig. 56-10B). Studies have reported diagnostic accuracy as high as 91.5%.^{82,83,88,91-97}

A barium enema study may also detect other pathologies of the small and large bowel that can mimic the clinical presentation of acute appendicitis. These include neoplasm, Crohn's disease, ileal diverticulitis, and cecal diverticulitis.^{82,83,88,91-97}

Barium enema is not without major drawbacks. Nonfilling of the appendix can be seen in 15% to 20% of normal patients,

Figure 56-8 Appendiceal abscess: plain radiographic findings.

This abscess manifests as a bubbly collection of extraluminal gas in the right lower quadrant.

and it may be difficult to differentiate a partially filled from a completely filled appendix. Also, a barium enema study provides only inferential information about extracolonic disease and cannot evaluate the nature of appendiceal phlegmons and abscesses. The appendix can also intussuscept (Fig. 56-12) into the cecum, producing a cecal defect unrelated to appendicitis.^{96,98-100}

Computed Tomography. Helical CT imaging has proven to be a highly effective and accurate means of diagnosing acute appendicitis, with reported sensitivities of 90% to 100%, specificities of 91% to 99%, accuracies of 94% to 98%, positive predictive values of 92% to 98%, and negative predictive values of 95% to 100%.¹⁰¹⁻¹⁰⁶ In addition to visualization of the appendix, CT can detect complications of appendiceal perforation, such as abscess or phlegmon (Fig. 56-13). Critically, CT can help diagnose many alternate conditions that might mimic the clinical presentation of acute appendicitis.¹⁰⁷

The goal of CT investigation in patients with right lower quadrant pain is to identify the normal or abnormal appendix. Thin-section (slice thickness ≤ 5 mm) imaging is now standard, providing superior sensitivity compared with older techniques.^{108,109} With the advent of multidetector scanners such as

Figure 56-9 Acute appendicitis causing partial small bowel obstruction. Upright radiograph shows dilation and air-fluid levels in multiple lower abdominal small bowel loops (b). The patient presented with fever and leukocytosis, and gangrenous appendicitis was found at surgery.

Figure 56-10 Principles of barium enema diagnosis of acute appendicitis. A. Only complete filling of the appendix to its bulbous tip excludes appendicitis. B. Ileocecal deformity (arrows) caused by appendiceal abscess or phlegmon. (From Bartram CI, Kumar P: *Clinical Radiology in Gastroenterology*. Oxford, Blackwell Scientific, 1981, p 219.)

The cecum and terminal ileum (open arrow) are unremarkable. **B.** Appendiceal abscess shows compression of the cecal caput, obstruction of the base of the appendix (solid arrow), and a spiculated lateral contour (open arrow) of the terminal ileum. C, cecum; I, ileum.

Figure 56-12 Partial appendiceal intussusception. The appendix is incompletely filled (solid arrow) and partially intussuscepting into the cecal caput (open arrow).

Figure 56-13 Perforated acute appendicitis with abscess. This coronal image from an enhanced CT scan shows extensive right lower quadrant inflammation and a fluid-filled abscess (arrows). Note the thickened, inflamed cecum (arrowheads).

16- and 64-slice multidetector CT (MDCT), high-quality multiplanar reformatted (MPR) images are now possible. Adding coronal reconstructions, for example, can improve appendix visualization and diagnostic confidence.^{110,111}

Radiologists are able to identify a normal appendix in most patients with abdominal pain who undergo abdominal CT (67%-100%), with a trend toward better visualization with thinner section imaging.^{109,112-114} Appendix identification is more difficult in patients with a paucity of retroperitoneal fat, in patients with ascites, and in women compared with men.¹¹²⁻¹¹⁴ With CT, the diameter of a normal appendix ranges from 3 to 10 mm.¹¹²⁻¹¹⁴ In one study, the normal appendix had a diameter more than 6 mm in 42% of cases.¹¹³ Therefore, an appendiceal diameter more than 6 mm is not alone sufficient for the diagnosis of acute appendicitis.

CT findings of appendicitis may include appendiceal distention, wall thickening, appendicolith, periappendiceal fat stranding, periappendiceal fluid, and abscess (Figs. 56-14 to 56-16).^{20,109,115,116} In early or mild cases, the appendix commonly appears as a fluid-filled, minimally distended tubular structure measuring 5 to 6 mm in diameter.²⁰ At this stage, the periappendiceal fat may have a normal appearance (Fig. 56-17).

Figure 56-14 Acute appendicitis on enhanced CT. The distended appendix (arrow) is seen in cross section and demonstrates abnormal mural thickening and enhancement. In addition, an intraluminal appendicolith (arrowhead) is present.

Over time, the appendix continues to distend, often measuring 7 to 15 mm in diameter. The appendiceal wall thickens circumferentially and enhances after intravenous (IV) contrast administration. The mural enhancement may be homogeneous or may exhibit a so-called target sign (Fig. 56-18). Periappendiceal inflammation, seen as stranding in the adjacent fat, is present in most patients.²⁰ Lack of IV contrast material limits visualization of mural thickening and mural enhancement in mild cases of appendicitis. As a result, noncontrast CT may result in a higher rate of false-negative interpretations.^{104,116-118} Many investigators consider periappendiceal inflammation a necessary imaging finding when diagnosing acute appendicitis with unenhanced CT imaging.^{101,102,104,105,117}

Inflammation of the appendix may also cause secondary reactive thickening of adjacent structures, including the wall of the terminal ileum or cecal caput. The cecal arrowhead sign refers to a triangular or arrowhead configuration of oral contrast material funneling into a focally thickened cecum, pointing toward the appendiceal orifice (Fig. 56-19). The cecal bar sign refers to linear inflammatory soft tissue at the base of the appendix that separates the contrast-filled cecum from the appendix.^{119,120} With perforated appendicitis, extraluminal air,

Figure 56-15 Acute appendicitis on enhanced CT. This coronal multiplanar reconstruction image shows the distended appendix (arrows) with multiple obstructing appendicoliths (arrowhead) at the appendiceal orifice. Note the mural wall thickening and enhancement, as well as the periappendiceal soft tissue stranding and fluid. On pathologic examination the appendix was shown to be perforated.

Figure 56-16 Acute appendicitis on CT. Although the appendix itself is not distinctly identified, there are three appendicoliths (arrows) present in association with right lower quadrant inflammation and pericecal thickening. This constellation of findings is diagnostic of acute appendicitis.

Figure 56-17 Acute appendicitis. The abnormal appendix (arrows) is seen in cross section on this enhanced CT scan. Although there is minimal distention of the appendiceal lumen, there is evidence for abnormal mural thickening and enhancement. Note the absence of periappendiceal inflammatory change.

marked ileocecal wall thickening, localized lymphadenopathy, pericecal phlegmon or abscess, peritonitis, and/or small bowel obstruction may be present (Fig. 56-20).¹²¹⁻¹²⁴

Appendicitis may also be confined to the distal appendix, a condition referred to as distal or tip appendicitis (Fig. 56-21). Distal appendicitis (in which at least 3 cm of the proximal appendix is normal) may affect as many as 8% of patients with appendicitis who undergo CT.¹²⁵

Computed Tomography Protocols. Conventional CT protocols for evaluating patients with suspected appendicitis

Figure 56-18 Acute appendicitis. The abnormal appendix (arrows) is seen in cross section on this enhanced CT study, which demonstrates a mural stratification pattern of enhancement with alternating high- and low-density rings caused by serosal and mucosal enhancement and submucosal edema.

Figure 56-19 Acute appendicitis on enhanced CT. The appendix (arrowheads) is distended, with enhancement of the thickened appendiceal wall and periappendiceal soft tissue stranding. Note the funneling of enteric contrast in the thickened cecum toward the appendiceal orifice, the so-called arrowhead sign (arrow).

Figure 56-20 Small bowel obstruction from acute appendicitis. **A.** There are multiple dilated small bowel loops in the pelvis to the level of the abnormally distended, thick-walled, and enhancing appendix (arrows). **B.** A more superior CT scan shows a calcified appendicolith (arrowhead) near the appendiceal orifice.

Figure 56-21 Distal or tip appendicitis. **A.** The proximal appendix (arrows) is normal in appearance on this enhanced CT scan. **B.** The distal aspect of the appendix demonstrates abnormal mural thickening and enhancement (arrows); periappendiceal soft tissue stranding is also present (arrowheads).

incorporate abdominal and pelvic imaging after administration of oral and IV contrast material. Many studies have focused on alternate CT protocols in an attempt to reduce radiation dose to the patient, eliminate the patient risks associated with contrast administration, and enable earlier scanning rather than waiting for bowel transit of oral contrast material. Investigated strategies include scanning without IV or oral contrast, using rectal contrast, targeted imaging of the right lower quadrant, and reduced radiation dose scanning techniques.^{4,105,118,126-132}

CT protocols may not include oral or IV contrast. A major advantage of this approach is the ability to scan symptomatic patients immediately without having to wait for oral contrast material ingestion and transit to the cecum. Eliminating IV contrast means avoiding risks of adverse reaction and nephrotoxicity. Noncontrast scans also have lower costs.

Without oral contrast, disadvantages include potential misinterpretation of another structure (e.g., a loop of bowel) as the appendix, or misinterpretation of an abnormal appendix or abscess as a bowel loop.^{117,133} Relative to a contrast-filled appendix, finding the normal appendix without oral contrast is more difficult. Finally, identification of bowel thickening and luminal narrowing, two hallmarks of GI disease on CT, is often very limited without contrast material filling the bowel lumen.¹³⁴

Without IV contrast, disadvantages include limited assessment of wall thickening, inability to assess enhancement, limited differentiation of the appendix from blood vessels, reduced sensitivity for perforation or complication,^{20,118,133,135} and a lesser ability to make an alternate diagnosis. Identification of wall thickening and enhancement is often critical in patients in whom fat stranding is not detected, either because there is a paucity of retroperitoneal fat or because appendicitis is early or mild.^{104,118} One study found that 15% to 22% of patients with proven appendicitis had no detectable periappendiceal inflammation on CT.¹¹⁸

Administration of rectal contrast material permits rapid filling of the cecum, with appendix identification in a large majority of cases. In a study by Rao and associates, use of a focused right lower quadrant technique with rectal contrast material enabled detection of the normal appendix in 94% of patients without appendicitis and visualization of part or all of the abnormal appendix in 96% of patients with acute appendicitis. In their study, 73% of the normal appendices filled with air or rectal contrast.¹⁰⁴ Disadvantages of the rectal contrast technique include the potential for increased patient discomfort,¹³¹ inability to instill rectal contrast material in patients with contraindications to its use, and risk of causing a hydraulic pressure effect and rupturing the appendix.¹³⁶ This technique may also fail if there is leakage of contrast material onto the CT

table or if there is inadequate opacification of the cecum. Wise and co-workers reported that colonic contrast material was not successfully advanced into the cecum in 18% of 100 patients who underwent focused appendiceal CT, usually because of abundant stool in the right colon.¹³¹ One study reported that rectal contrast use resulted in a reduced length of patient stay in the emergency room without significant impact on patient satisfaction or comfort.¹³⁷

The goal of focused scanning is to reduce the portion of the abdomen and pelvis that is scanned, thereby reducing overall radiation dose to the patient. Although early studies showed that focused techniques may have comparable diagnostic accuracy,¹⁰⁵ later investigations found an overall reduction in diagnostic performance. By using a focused technique, the appendix may not be visualized or may only be partially visualized. In addition, evidence of an alternate diagnosis may be excluded from the field of view.¹¹⁸ Brassart and colleagues compared scanning of the whole abdomen and pelvis with focused scanning below the iliac crests in the same set of 152 adult patients by generating two sets of images from the raw data.¹³⁸ They found that the focused technique resulted in exclusion of the appendix from view in 5% of patients and a reduced likelihood of giving a correct diagnosis (from 78%-68%). Common alternative diagnoses include acute gynecologic disorders, inflammatory bowel disease, small bowel obstruction, infectious disorders of the GI tract, and urinary tract conditions.^{45,107}

As of 2013, the consensus position of the American College of Radiology (ACR) expert panel is that IV contrast is preferred but not mandatory when using CT to evaluate for suspected appendicitis in adult patients. The use of oral or rectal contrast is left to institutional preference. For atypical presentations in patients older than 14 years, the use of IV contrast is relatively more valuable. In this group, ultrasound evaluation may be of similar value to noncontrast CT. In pregnant patients and children younger than 14 years, ultrasound is considered first-line imaging. When CT is used, IV contrast is preferred, whereas oral and rectal agents are again left to institutional preference. Magnetic resonance imaging (MRI) evaluation is gaining popularity as the technology evolves, particularly in pregnant patients or those in whom US is inconclusive.⁴⁵

Ultrasonography. Puylaert's introduction of the graded compression ultrasound technique in the 1980s has substantially improved sonographic identification of the appendix.¹³⁹ US is widely available, noninvasive, relatively inexpensive, and poses no ionizing radiation risk to the patient. This latter feature is a major consideration in the most radiation-sensitive individuals, children and pregnant women.¹²⁸

Important limitations of US are reduced sensitivity in obese patients, inability to image beyond bowel gas, technical difficulties in patients with severe pain, and dependence on operator skill. Poor penetration in the obese population limits widespread use of this technique in North America and parts of Europe. Although some authors have reported that the normal appendix is visible in 64% to 72% of patients, others have noted a visualization rate of only 0% to 4% in adult patients, regardless of technique.^{140,141}

The reported diagnostic accuracy of ultrasound varies, depending on the patient population studied. A meta-analysis comparing CT and US in a broad age range found an overall ultrasound sensitivity of 78% and specificity of 83%.¹⁴² A large

study of children aged 3 to 18 years found sensitivity and specificity of 73% and 97%, respectively.¹⁴³

Adherence to optimal scanning techniques is critical. Sagittal, transverse, and oblique imaging should be performed in the abdomen and pelvis, with the addition of a transvaginal examination in women in whom the diagnosis is not clear following the transabdominal approach. A high-frequency linear or curvilinear transducer may be used, depending on the patient's body habitus. A high-frequency transducer typically offers the best image resolution, but a curvilinear probe may be better suited for imaging patients with a poorly compressible right lower quadrant bowel, large patients with their cecum and appendix located deep within the pelvis, patients with poorly defined right lower quadrant anatomy, and patients with a retrocecal or perforated appendix.

The technique of graded compression should be used to displace or compress gas-filled bowel loops in the field of view. This maneuver aids identification of the maximal point of tenderness while helping differentiate abnormal, noncompressible bowel loops or the inflamed appendix from those normally compressible structures. Also, the maintenance of slow and gentle pressure facilitates completion of the examination in uncomfortable and apprehensive patients.²⁰

Color Doppler evaluation may add valuable information by demonstrating hyperemia in the inflamed appendix or bowel wall.¹⁴⁰ This can aid diagnosis in patients with equivocal gray-scale results.

Sonographically, the abnormal appendix appears as a blind-ending, noncompressible, tubular structure larger than 6 mm in diameter with a laminated wall (Figs. 56-22 to 56-24). Progressive ischemia and infarction of the appendiceal wall lead to focal or diffuse loss of definition of the wall layers.¹⁴⁴ Hyperemia may be demonstrated on color Doppler evaluation, but decreased or absent flow may be seen in cases of gangrenous

Figure 56-22 Sonogram of an inflamed appendix containing an appendicolith. Longitudinal image shows a thick-walled, fluid-filled appendix (A). The layers of the appendiceal wall are not well defined. An appendicolith (large arrow) is identified as an echogenic focus with acoustic shadowing (small arrows).

Figure 56-23 Correlation of sonography and CT findings in acute appendicitis. **A.** CT scan shows the abnormally distended and thick-walled appendix (arrows) with periappendiceal inflammation. Note the reactive inflammatory thickening of the terminal ileum (arrowhead) and the cecum. **B.** Longitudinal transvaginal sonogram shows a thick-walled, distended appendix (arrows). **C.** Transverse transvaginal sonogram shows the thick-walled and abnormally distended appendix (arrows). The appendiceal diameter was 13 mm.

Figure 56-24 Ultrasound of appendicitis with periappendiceal fluid. **A.** Longitudinal imaging with graded compression in a 7-year-old girl demonstrates a dilated appendix with a diameter of 9 mm (cursors). Wall stratification is maintained, and periappendiceal fluid (F) is visualized.

appendicitis.²⁰ With perforation, localized disruption of the appendiceal wall may be seen, and extraluminal pockets of gas may be present. Appendicoliths appear as rounded echogenic foci with clean distal acoustic shadowing, and their presence is highly associated with appendicitis.

In addition to the appendiceal findings present in acute appendicitis, recognition of characteristic periappendiceal findings can aid in its diagnosis and differentiation from other conditions. Inflammation of the periappendiceal fat appears as an echogenic region that may cause mass effect and separate the

inflamed bowel segment(s) from surrounding structures.²⁰ Periappendiceal phlegmon appears as hypoechoic, poorly marginated regions within the fat adjacent to the appendix, and abscesses can be recognized as focal collections of fluid that may or may not contain gas. Reactive inflammatory thickening of the cecal or terminal ileal wall may also be present in patients with appendicitis.

Despite performance of optimized US examinations, US sensitivity for diagnosing perforated appendicitis is lower than that for nonperforated appendicitis. Overall, the noncompressible appendix is visible in only 38% to 55% of patients with perforated appendicitis.^{145,146}

As of 2013, ACR Appropriateness Criteria guidelines recommend ultrasound as the first-choice imaging technique in pregnant women and children younger than 14 years with suspected appendicitis.⁴⁵

Magnetic Resonance Imaging. Recent advances in MRI technology have led to an increased role in the setting of suspected appendicitis. Superior soft tissue contrast resolution, multiplanar imaging capability, and ability to scan without contrast administration make MRI an attractive choice. Unlike CT, MRI does not involve the use of ionizing radiation.¹⁴⁷ Drawbacks to the use of MRI include relatively long imaging times, higher cost, higher dependence on technique for good results, and reduced availability relative to CT.⁵⁷

Successful MRI protocols limit motion artifact and emphasize soft tissue contrast in the region of the appendix. Published protocols typically include single-shot fast spin-echo (SSFSE) sequences with T2 weighting in axial, coronal, and sagittal planes, at least one plane with SSFSE T2 with fat suppression, and one or more planes of T1-weighted imaging.¹⁴⁸ Multiple studies have reported the highest appendix visualization rate with T2-weighted images.^{47,149,150} Others have shown improved sensitivity for acute appendicitis by including a diffusion-weighted sequence.^{151,152}

With MRI, the normal appendiceal walls are isointense to muscle on T1- and T2-weighted images. Luminal contents such as air are typically T1 and T2 hypointense.^{149,153} In pregnant patients, the appendix tends to migrate superiorly in the abdomen over time, often extending superior to the iliac crest by the third trimester.^{154,155}

MRI findings of acute appendicitis include a dilated appendix (>7 mm) filled with T2 hyperintense fluid, wall thickness more than 2 mm, and T2 hyperintense inflammation or fluid in the periappendiceal fat (Fig. 56-25).^{46,151,156,157} The thickened appendiceal wall may also be hyperintense on T2-weighted imaging. MRI is indeterminate if the appendix measures 6 to 7 mm in diameter and contains T2 hyperintense fluid without evidence of wall thickening or a periappendiceal fluid signal.^{46,153}

Although reduction or elimination of ionizing radiation is always desirable, the use of MRI for suspected appendicitis has grown most rapidly in patients for whom radiation concerns are most pronounced, notably pregnant women and pediatric patients.⁴⁵ US remains the initial imaging test of choice in these patients,⁴⁵ but the use of MRI has been growing in popularity, particularly when ultrasound examinations are inconclusive.¹⁵⁸ At one institution, integrating MRI into the workup for suspected appendicitis in pregnant women resulted in a 47% reduction in the negative laparotomy rate (from 55%-29%).¹⁵⁹ Some early studies comparing the two modalities have found better overall diagnostic performance with MRI, suggesting that MRI use may continue trending upward.¹⁶⁰⁻¹⁶²

The clinical diagnosis of acute appendicitis can be more challenging in pregnant patients because of anatomic considerations, presence of leukocytosis in otherwise normal patients, and wide range of alternate pathologies.^{45,59,163} Early studies¹⁶⁴ reported right upper quadrant pain to be the typical presentation of acute appendicitis during pregnancy, with the appendix migrating superiorly as the uterus enlarges.¹⁶⁵ However, more recent investigations have found that right lower quadrant pain remains the most common presenting symptom, even in this patient population.¹⁶⁶

Despite early reports, most recent studies have found poor sensitivity for ultrasound in the diagnosis of acute appendicitis during pregnancy.¹⁶⁷ In a large study by Pedrosa and colleagues,

the normal appendix was only visualized in 2 of 126 pregnant patients without appendicitis ($<2\%$). In patients with appendicitis, sensitivity was only 36% (5 of 14).¹⁵⁷ In another smaller study, US could not identify the appendix in 92% of pregnant patients.³⁶

Theoretical risks to the fetus of MRI during pregnancy include heat deposition, acoustic damage, and gadolinium toxicity. When MRI heat deposition was studied in a pig model, results showed no significant change in amniotic fluid temperature.¹⁶⁸ During an MRI examination, rapid current switching within the gradient coils creates substantial acoustic noise. In clinical use, maximum noise tends to be generated during echoplanar imaging (e.g., diffusion sequences) because of the high-gradient amplitudes and rapid switching required.¹⁶⁹ Despite the theoretical concerns, studies following children exposed to echoplanar MRI in utero did not demonstrate a significant increase in postnatal disease or disability.^{170,171} MRI vendors have begun introducing scanners with reduced acoustic noise.¹⁷² This may help alleviate safety concerns while improving patient comfort and, as a result, motion degradation.¹⁷³⁻¹⁷⁵ Despite the theoretical risks of MRI to the fetus, no studies have shown deleterious long-term effects. MRI has long been used in the obstetric population to evaluate fetal anomalies, without known adverse effects.¹⁷⁶⁻¹⁷⁸

Gadolinium toxicity has garnered attention as our understanding of nephrogenic systemic fibrosis continues to evolve. In the pregnant female, IV gadolinium-based contrast crosses the placenta and is filtered by the fetal kidneys. Subsequently, the gadolinium agent is excreted into the amniotic fluid, where some of it remains in contact with the fetus for a prolonged period. Because there is more time inside the body, there is more time for the chelated agent to break down and release the free gadolinium, which has been implicated in toxicity events.¹⁷⁹⁻¹⁸²

Based on this physiology, the U.S. Food and Drug Administration has classified gadolinium-based contrast agents as category C agents. The 2013 ACR guidance document on safe MR practices stated that "The risk to the fetus of gadolinium-based MR contrast agent administration remains unknown and may be harmful."¹⁸³

Figure 56-25 MRI scans of acute appendicitis during pregnancy. **A.** Axial T2-weighted HASTE imaging shows a dilated, fluid-filled appendix (arrow) surrounded by low signal fat stranding. There are multiple low signal fecaliths within the appendiceal lumen (arrowheads). **B.** A coronal HASTE image shows the dilated appendix and fecalith (arrow). **C.** In a second patient, sagittal T2-weighted HASTE imaging shows the appendix, with marked, low-signal wall thickening (arrow).

IV gadolinium is not routinely used when using MRI to evaluate for suspected appendicitis.¹⁴⁸ Fortunately, recent studies have demonstrated a similar level of diagnostic accuracy using contrast-enhanced CT and noncontrast MRI to detect acute appendicitis in the pregnant population.^{147,184} A meta-analysis by Blumenfeld and associates noted sensitivity, specificity, and positive and negative predictive values of MRI for diagnosing appendicitis during pregnancy as 95.0%, 99.9%, 90.4%, and 99.5%, respectively, when scans of diagnostic quality were reviewed.¹⁸⁵

DIFFERENTIAL DIAGNOSIS

The presence of inflammatory change adjacent to the cecum is typical of acute appendicitis but is not specific for the diagnosis. The differential diagnosis includes cecal or ileal diverticulitis, Crohn's disease, mesenteric adenitis, epiploic appendagitis, inflamed Meckel's diverticulum, infectious or ischemic ileitis, typhlitis, perforated cecal carcinoma, and pelvic inflammatory disease.

Identification of the normal appendix can facilitate an appropriate alternate diagnosis. The distinction can be critical because, unlike appendicitis, many of the other conditions are treated conservatively.

Mesenteric Adenitis

Mesenteric adenitis is the second most common cause of right lower quadrant pain after acute appendicitis, accounting for 2% to 14% of discharge diagnoses in patients suspected of having appendicitis.¹⁸⁶⁻¹⁸⁹

Primary mesenteric adenitis is diagnosed by CT or US when there are more than three right-sided mesenteric lymph nodes 5 mm or larger without an identifiable acute inflammatory process or with mild (<5-mm) terminal ileal wall thickening. Mesenteric nodes should not be considered responsible for the patient's symptoms unless a primary intestinal inflammatory lesion is excluded. Underlying infectious terminal ileitis is thought to be responsible for most cases of primary mesenteric adenitis.^{186,187,189}

In secondary mesenteric adenitis, the enlarged mesenteric lymph nodes are related to an identifiable underlying condition. Possible causes include acute appendicitis, infectious enteritis or enterocolitis, diverticulitis, Crohn's disease (Fig. 56-26), celiac disease, and neoplasia.¹⁸⁹

Infectious Enterocolitis

Infectious enterocolitis, especially bacterial ileoceitis caused by *Yersinia* spp., *Campylobacter*, or *Salmonella*, can present with symptoms similar to those of acute appendicitis. Imaging studies reveal terminal ileal and cecal wall thickening in association with moderate right lower quadrant mesenteric adenopathy.¹⁹⁰

Crohn's Disease

Crohn's disease is characterized by transmural granulomatous infiltration of the bowel that results in wall thickening secondary to edema, fibrosis, inflammation, and lymphangiectasis. CT is useful in the identification of inflamed segments of bowel in this disease; the terminal ileum and right colon are most commonly affected (Fig. 56-27). The most frequent CT finding in Crohn's disease is homogeneously enhancing thickened bowel, although a mural stratification pattern may be

Figure 56-26 Mesenteric adenitis in a patient with Crohn's disease. Enhanced CT scan shows multiple, enlarged, right lower quadrant nodes (arrows) in this patient with Crohn's disease. The appendix was identified (arrowheads) and was normal.

present. The average degree of mural thickening has been noted to range from 11 to 30 mm.¹⁹¹⁻¹⁹⁵ The distribution of bowel involvement is commonly segmental, with interposed loops of normal bowel.

CT is also useful for identifying the many potential complications of this disorder. These include the formation of bowel strictures, mesenteric pathology (e.g., fibrofatty proliferation, inflammation, abscesses, and adenopathy), fistula and sinus tract formation (Fig. 56-28), superimposed neoplasm, renal and gallbladder calculi, hepatic and biliary disease (including hepatitis and pericholangitis), and sacroiliitis.

Epiploic Appendagitis

Primary epiploic appendagitis is the result of ischemia, torsion, or infarction of an epiploic appendage. This self-limiting condition results in focal abdominal pain that can simulate appendicitis when it occurs in the right lower quadrant. It is estimated to be the cause in approximately 1% of patients suspected of having appendicitis.¹⁹⁶ On CT, the inflamed appendage is identified as a round or ovoid fat density structure surrounded by a thickened, high-attenuation rim of thickened visceral peritoneum (Fig. 56-29). A central high-attenuation focus representing a thrombosed vessel or hemorrhage may also be present. Thickening of the adjacent colonic wall is commonly present, along with inflammatory changes in the adjacent fat.

Omental Infarction

An omental infarction is a benign, self-limiting condition caused by torsion or infarction of the greater omentum. Males are affected twice as often as females, and the infarction is usually right-sided.¹⁹⁷ On CT, an omental infarction appears as an inflammatory mass containing variable amounts of fat and fluid (Fig. 56-30). Inflammatory change and small amounts of peritoneal fluid are commonly seen surrounding the omental infarction. The size of the infarct is typically larger than that of an inflamed epiploic appendage; it is more heterogeneous in appearance and lacks a surrounding hyperattenuating rim. Sonographically, an omental infarction appears as a hyperechoic, noncompressible, ovoid mass adherent to the peritoneum.

Figure 56-27 Crohn's disease. **A.** This enhanced CT scan shows circumferential mural thickening of the terminal ileum (arrows). **B.** A more cephalad image shows associated fibrofatty proliferation (F) of the mesentery.

Figure 56-28 Crohn's disease with enteroenteric fistulas. This enhanced CT scan shows circumferential thickening of ileal loops with multiple linear soft tissue tracts extending between the loops representing interloop (enteroenteric) fistulas (arrowheads). Fibrofatty proliferation is also present in the mesentery.

Right-Sided and Ileal Diverticulitis

Right-sided diverticulitis is caused by inflammation of a colonic diverticulum in the cecum or ascending colon. Unlike sigmoid diverticula, right-sided diverticula are usually true diverticula that contain all layers of the colonic wall. Identification of an intramural abscess or cecal diverticulum in association with an inflammatory process located cephalad to a normal-appearing cecal caput and periappendiceal region should suggest the diagnosis. The characteristic findings on US and CT examination are identification of the inflamed diverticulum in association with focal, asymmetric, colonic wall thickening and inflammation of the pericolonic fat (Fig. 56-31).

Figure 56-29 Right-sided epiploic appendagitis. On enhanced CT, the inflamed epiploic appendage (arrows) is identified as a homogeneous oval structure surrounded by a thickened, high-attenuation rim of visceral peritoneum contiguous with the ascending colon.

Ileal diverticulitis presents as a focal inflammatory mass or thickening of the terminal ileum with a variable mesenteric inflammatory reaction surrounding an inflamed ileal diverticulum. Acquired ileal diverticula have been reported in 1% to 2% of small bowel series using spot compression radiography.¹⁹⁸

Meckel's Diverticulum

Meckel's diverticulum is a true diverticulum arising from the distal ileum. It is the most common congenital anomaly of the small bowel, affecting approximately 2% of the population.⁶¹

On imaging, an inflamed Meckel's diverticulum appears as a variable-sized, blind-ending structure contiguous with the distal ileum (Fig. 56-32). Generally, the diverticulum itself cannot be identified but the diagnosis can be considered when inflammatory changes are seen adjacent to the distal ileum.

Neutropenic Colitis (Typhlitis)

This type of colitis occurs in profoundly neutropenic patients (especially patients with acute leukemia who are receiving chemotherapy) and results in necrotizing injury to the involved bowel. The inflammatory process may involve the cecum, ascending colon, ileum, or appendix. CT findings are nonspecific and include concentric homogeneous or heterogeneous thickening of the bowel wall, with associated intramural edema and necrosis, pericolic fluid, thickening of the pericolic fascia, and pneumatosis intestinalis (Fig. 56-33).¹⁹⁹ Prompt diagnosis

Figure 56-30 Right-sided omental infarct. A heterogeneous inflammatory mass (arrows) composed of fat and soft tissue elements is identified in the right lower quadrant; this represents an omental infarct. The omental infarct is causing displacement of pelvic small bowel loops toward the left abdomen.

is essential to prevent transmural necrosis and subsequent perforation.

Ischemia

Ischemia of the distal small bowel or the right colon may cause localized right lower quadrant pain. Most cases will be caused by a superior mesenteric artery thrombus or embolus or by low perfusion pressure.⁶¹

On enhanced CT examination, the affected bowel will initially demonstrate circumferential bowel wall thickening (Fig. 56-34). A mural stratification pattern is often seen after IV contrast administration. With bowel infarction, pneumatosis intestinalis may develop, and the bowel wall may demonstrate lack of enhancement with IV contrast administration.

Cecal Carcinoma

Cecal carcinoma usually presents as asymmetric nodular mural thickening (typically >1 cm) or a soft tissue attenuation mass (Fig. 56-35). Obstruction of the appendiceal orifice by the mass may lead to the development of appendicitis and appendiceal perforation.^{200,201}

Crohn's Disease

Crohn's disease may involve any part of the GI tract. Involvement of the appendix results in a granulomatous appendicitis that is usually managed conservatively. Pathologic studies have shown appendiceal involvement in 20% to 36% of patients with Crohn's disease (Fig. 56-36).²⁰² Histopathologically, the inflammatory appendiceal changes in Crohn's disease are similar to changes in other intestinal segments involved by this entity—transmural inflammation with wall thickening, epithelioid granulomas, lymphoid aggregates, and mucosal ulcerations.²⁰³

Figure 56-31 Right-sided diverticulitis. A. This enhanced CT scan shows the inflamed diverticulum (arrow) in the proximal ascending colon with surrounding inflammatory changes and associated reactive lateral colonic wall thickening. **B.** This slightly more caudal image shows the normal appendix (curved arrow) medial to the inflamed right colon.

Figure 56-32 Inflamed Meckel's diverticulum. There is a thick-walled, blind-ending tubular structure adjacent to the terminal ileum (arrows) that represents the inflamed Meckel's diverticulum. Inflammatory changes are also identified in the surrounding mesenteric fat.

Figure 56-33 Neutropenic colitis (typhlitis) in a patient with acute myelogenous leukemia. There is circumferential mural thickening of the cecum (arrows) and terminal ileum (arrowheads) along with mild perienteric inflammatory change.

Although Crohn's disease frequently causes chronic abdominal symptoms, up to one third of patients with ileocecal Crohn's disease present with right lower quadrant symptoms mimicking those of appendicitis.²⁰⁴

Ripolles and co-workers evaluated 190 patients with Crohn's disease with gray-scale and color Doppler US and found that 20% had appendicular involvement.²⁰² They also found that appendiceal involvement of Crohn's disease was always associated with segmental ileal and/or cecal thickening. There were no cases of isolated appendiceal involvement in their series.

They found that in patients with isolated ileocecal region involvement, terminal ileal wall thickening more than 5 mm and color Doppler flow in the ileum were the most valuable US features for differentiating Crohn's disease from acute appendicitis (positive and negative predictive values as high as 96% and 74%, respectively). Also, they found that irregular thickening of the submucosal layer of the terminal ileum and fibrofatty proliferation of the mesentery around the inflamed terminal ileum were specific findings of Crohn's disease that were absent in acute appendicitis.²⁰²

Isolated appendiceal involvement, also known as idiopathic granulomatous appendicitis, is now believed by many to be a distinct entity from Crohn's disease with appendiceal involvement. Patients with this condition commonly present with symptoms mimicking those of acute appendicitis. Idiopathic granulomatous appendicitis is characterized pathologically by the presence of numerous granulomas and concentric mural fibrosis.²⁰⁵ The histopathologic feature of numerous granulomas differentiates this entity from Crohn's disease, which characteristically has sparse granulomas. Also, unlike patients who have involvement of the appendix from Crohn's disease, patients with idiopathic granulomatous appendicitis rarely have recurrence, fistulization, or extra-appendiceal GI tract involvement after appendectomy.²⁰⁵

Ulcerative Colitis

Ulcerative colitis is characterized by colonic mucosal inflammation and ulceration that typically proceeds in a continuous fashion from the rectum proximally. CT shows bowel wall thickening caused by a combination of infiltration of the lamina propria by round cells, hypertrophy of the muscularis mucosa with resultant separation of the mucosa from the submucosa, and deposition of submucosal fat.¹⁹⁴ The mean bowel wall thickness in ulcerative colitis is approximately 8 mm.^{192,195} In contradistinction to Crohn's disease, which typically shows homogeneous enhancement of the colonic wall after IV contrast administration, approximately 70% of patients with ulcerative colitis demonstrate inhomogeneous mural enhancement after IV contrast administration (Fig. 56-37).^{194,195}

Appendiceal involvement is seen in 61% to 87% of patients with pancolitis caused by ulcerative colitis.²⁰³ The appendiceal involvement may be contiguous with cecal ulcerative colitis or may occur as a skip lesion adjacent to a normal cecum. This latter type has been referred to as ulcerative appendicitis. Appendiceal involvement was found to occur as a skip lesion without associated cecal involvement in 34% to 86% of colons removed for chronic ulcerative colitis.²⁰⁶

On CT examination, the typical features of ulcerative appendicitis are edema and thickening of the appendiceal wall. Appendectomy is thought to be a protective factor in ulcerative appendicitis.²⁰⁶

Endometriosis

GI tract involvement is seen in 5% to 37% of patients with endometriosis. The most commonly involved segments, in order of decreasing frequency, are the rectum and sigmoid colon, small bowel, cecum, and appendix.

Most patients with endometriosis of the appendix will remain asymptomatic. Symptomatic patients usually experience chronic pain; however, some patients may experience acute

Figure 56-34 Small bowel ischemia due to thrombosis of the superior mesenteric vein. **A.** This enhanced CT scan shows circumferential thickening of ileal small bowel loops within the pelvis. Pelvic ascites (A) is also present. **B.** There is absent enhancement of the superior mesenteric vein (arrow) caused by intraluminal thrombus.

Figure 56-35 Cecal carcinoma. This lobulated, nodular cecal mass causing eccentric wall thickening of more than 1 cm (arrows) was pathologically proven to be a primary cecal adenocarcinoma.

right lower quadrant pain that is clinically indistinguishable from that of acute appendicitis. On CT, a noninflamed, nondistended, and nonopacified appendix is frequently seen.²⁰³

Appendiceal Diverticulitis

Appendiceal diverticula are found in 0.004% to 2.8% of surgical and pathologic specimens.²⁰³ Most are acquired because of intrinsic mural weakness or abnormally raised intraluminal pressure secondary to increased muscular activity or closed

loop obstruction.²⁰⁷⁻²⁰⁹ The diverticula may be solitary or multiple and are found anywhere along the appendix. They are usually 0.2 to 0.5 mm.²⁰³

The presence of appendiceal diverticula may predispose to hemorrhage and diverticulitis. On CT, inflammation of the diverticulum and/or appendix is seen. Clinically, patients can present with symptoms similar to those of acute appendicitis. The pain is often intermittent and insidious and typically occurs 1 to 14 days before presentation. Because the risk of appendiceal perforation in appendiceal diverticulitis is fourfold greater than that for simple appendicitis, prompt surgical resection is advised.²⁰³ Accordingly, some surgeons recommend prophylactic appendectomy when diverticula are discovered during laparotomy for other disorders.^{207,208,210}

Appendiceal Intussusception

Intussusception of the appendix can present clinically in five different ways²¹¹⁻²¹⁴: (1) acute appendicitis; (2) intussusception; (3) recurrent intermittent right lower quadrant pain; (4) intermittent painless rectal bleeding; and (5) asymptotically, with incidental findings at laparotomy, barium enema, or colonoscopy. In the past, appendiceal intussusception was considered rare, being found in only 0.01% of surgical cases. However, the fifth presentation is probably the most common.

Most cases of significant appendiceal intussusception occur in children and are attributed to abnormal peristalsis caused by intraluminal or intramural irritants of the appendix. These include fecaliths, foreign bodies, endometriosis, lymphoid hyperplasia, carcinoid, adenocarcinoma, and mucocoeles.²¹¹⁻²¹⁴

On double-contrast barium enema examination, intussusception causes a characteristic coiled spring appearance of the cecum with nonfilling of the appendix. These findings are best seen en face. In incidental cases, the intussusception usually disappears on delayed overhead or postevacuation films. The coiled spring appearance can also be seen in appendicitis, but it is fixed in these cases, and the patient is symptomatic in the right lower quadrant. There may be only partial intussusception of the appendix, which produces an intraluminal filling defect

Figure 56-36 Crohn's disease with involvement of the appendix. **A.** There is circumferential wall thickening of the terminal ileum with mucosal hyperenhancement (arrow). The appendix is distended (arrowheads). **B.** On coronal reformatted imaging, the terminal ileum is thickened with mucosal hyperenhancement (arrows).

Figure 56-37 Ulcerative colitis. Enhanced CT scan shows a pancolitis with heterogeneous circumferential wall thickening of the cecum, transverse colon, and descending colon (arrows).

on the medial wall of the cecum and nonfilling of the appendix. The defect may be mistaken for a polyp (Fig. 56-38).²¹¹⁻²¹⁴ On US, the intussusception appears as multiple hypoechoic and hyperechoic rings, similar to intussusceptions elsewhere in the gut.^{211,213}

Hydrostatic reduction of appendiceal intussusceptions has been successful in children and adults. Asymptomatic transient intussusceptions probably do not require therapy or an extensive work-up, however.²¹¹⁻²¹⁴

Appendiceal Neoplasms

Primary neoplasms of the appendix are identified in 0.5% to 1% of appendectomy specimens at pathologic evaluation.²¹⁵⁻²¹⁷ The vast majority of these occur in adults older than 30 years. Of patients with appendiceal tumors, 30% to 50% will present with symptoms of appendicitis, and most of these will have obstruction of the appendiceal lumen by the tumor.^{216,218} Similarly, cecal carcinomas can obstruct the appendiceal lumen, resulting in secondary appendicitis. A study by Peck showed that 11% of right-sided colon cancers clinically presented as

appendicitis, most of which were caused by appendiceal inflammation from obstruction.²¹⁹

Preoperative identification of an appendiceal or cecal neoplasm may change the surgical approach (laparoscopic vs. an open procedure) and procedure performed (appendectomy vs. right hemicolectomy). CT has proven very useful in this regard. In a retrospective review of 22 CT scans in patients with pathologically proven primary appendiceal neoplasms, Pickhardt and colleagues found that the sensitivity of CT for tumor detection was 95% when morphologic appendiceal changes or a threshold appendiceal diameter of 15 mm was used as a diagnostic criterion. In 95% of these patients, soft tissue stranding of the peri-appendiceal fat was also present.²¹⁸

MUCOCELE

Epidemiology, Cause, and Pathology

Mucocele of the appendix is a descriptive term used to indicate dilation of the appendiceal lumen by mucinous secretions. The accumulation of mucin is slow and, if infection does not intervene, the appendix becomes a large, thin-walled, mucin-filled cystic structure.²²⁰⁻²²⁸ Mucoceles are uncommon; they are found in 0.3% of appendectomy specimens, with a 4:1 preponderance in females and a mean age of 55 years at presentation.²²⁸

Histologically, mucoceles are classified into three groups—focal or diffuse hyperplasia, mucinous cystadenoma, and mucinous cystadenocarcinoma. A number of obstructing lesions can lead to mucocele formation, such as postappendicitis scarring (most common), fecalith, appendiceal carcinoma, appendiceal endometrioma, appendiceal carcinoid, carcinoma of the cecum or ascending colon, appendiceal polyp, and appendiceal volvulus. It is unclear whether the cystadenoma or cystadenocarcinoma causes obstruction of the lumen as well or whether the mucosa of the obstructed appendix undergoes neoplastic change. Benign causes of obstruction outnumber malignant causes by a ratio of 4:1 to 10:1.^{222,225,226,229-231}

Most mucoceles are between 3 and 6 cm in diameter. Calcifications may occur in the wall or lumen of the mucocele.^{220,221,223,225,226} Myxoglobulosis is a rare variant in which numerous small globules form in the appendix. They may calcify and produce numerous 1- to 10-mm round or oval mobile

Figure 56-38 Appendiceal intussusception. **A.** Initial barium enema examination reveals a filling defect in the lower cecum that was interpreted as a polypoid mass (arrows). Colonoscopy performed several days later revealed no abnormalities. **B.** Subsequent barium enema examination shows a normal retrocecal appendix (arrows).

calcifications in the right lower quadrant. In myxoglobulosis, the appendiceal lumen has the consistency of tapioca or fish eggs.^{232,233}

Clinical Findings

The dominant complaint is chronic right lower quadrant pain in up to 64% of patients with mucocèles. Almost 23% of patients are asymptomatic. Abdominal swelling, anemia, or a mucous fistula may also be present. Physical examination reveals right lower quadrant tenderness in 38% and a palpable mass in 18% to 50% of patients.^{222,223,225,226,228-231}

The major clinical significance of a mucocèle lies in its complications; these include rupture or leakage leading to pseudomyxoma peritonei, torsion with gangrene and hemorrhage, and intussusception into the cecum, causing various degrees of bowel obstruction. If pseudomyxoma peritonei results from rupture of a benign mucocèle, the prognosis is good with simple removal of the fluid. When it results from a malignant process, it behaves like an invasive neoplasm with adhesions, bowel obstruction, and a 5-year survival rate of only 25%. Because cystadenoma and cystadenocarcinoma are usually indistinguishable radiologically, clinically, and on gross inspection, the surgeon must be warned preoperatively of the presence of a mucocèle.^{234,235}

Radiologic Findings

Plain Radiographs. The plain abdominal radiograph may be normal or may show a well-defined right lower quadrant mass. Rimlike calcifications help establish the diagnosis but are uncommon. In myxoglobulosis, mobile calcifications may be present that must be differentiated from phleboliths, calcified mesenteric lymph nodes, and calcified metastases to the medial wall of the cecum.^{82-84,225,226,230}

Barium Enema. The appendix fails to fill on barium enema examination, and the cecum is indented on its medial aspect by a smooth-walled mass. The cecum is distensible but inseparable

from the mass (Fig. 56-39). The terminal ileum is often displaced as well.^{82-84,225,226,230}

Cross-Sectional Imaging. On US, mucocèles manifest as fluid-filled masses that may be completely anechoic or may have septations and gravity-dependent echoes. These latter findings probably result from inspissated mucoid material that develops as the mucocèle ages and matures. Increased through-transmission is characteristic.^{229,231}

On CT, mucocèles appear as water density or, less often, soft tissue density masses (Fig. 56-40). Calcification may be seen within the wall or lumen (Fig. 56-41).

On MRI, when mucocèles contain predominantly fluid, they have long T1 and T2 relaxation times and low signal intensity on T1-weighted images and high signal intensity on T2-weighted images (Fig. 56-42). If their mucin content is high, mucocèles have short T1 and long T2 times, so they appear intense on both T1- and T2-weighted images.

When pseudomyxoma peritonei develops, malignant-appearing ascites with loculated fluid collections, septations, small calcifications, and a scalloped contour of the liver and spleen are visualized (Fig. 56-43).²³⁶⁻²³⁹ Mucin-producing adenoma, cystadenoma, or mucinous cystadenoma presents as an encapsulated, low-attenuation cyst and cannot be differentiated from a retention mucocèle.²²⁴

Differential Diagnosis

The differential diagnosis for these imaging findings includes ovarian cysts and neoplasms, duplication cyst, mesenteric and omental cysts, mesenteric hematoma or tumor, and abdominal abscess.

MUCINOUS CYSTADENOMA AND CYSTADENOCARCINOMA

The detection of a heterogeneously attenuated mass with nodular areas of soft tissue density or of a cystic mass with

Figure 56-39 Mucocoele of the appendix. **A.** Barium enema study shows a sharply contoured large intraluminal cecal defect (M). Note that the intussuscepting mucocoele arises from the tip of the cecum (c) and the appendix is not filled (arrows). **B.** CT scan shows the pericecal extension of the mucus-filled, distended appendix (arrow). Note that there is no periappendiceal inflammation. **C.** Gross specimen reveals a markedly distended, mucus-filled appendix compressing the base of the cecum. Pathologic study showed benign mucocoele.

Figure 56-40 Mucocoele of the appendix. This ovoid-shaped fluid-filled mass (arrows) represents an appendiceal mucocoele that is causing a mass effect on the adjacent cecum.

Figure 56-41 Mucocoele of the appendix. This ovoid-shaped, fluid-filled appendiceal mucocoele contains mural calcifications (arrows).

Figure 56-42 Mucocoele of the appendix visualized by CT and MRI. **A.** CT scan shows a triangular, fluid-filled distended appendix (A). The appendix has a sharp outer contour, and there is no periappendiceal inflammation. **B.** T1-weighted MR image (250/15) obtained at the same level reveals a distended appendix of low signal intensity. **C.** T2-weighted MR image (2000/60) shows a bright structure of high signal intensity, representing the appendix, indicative of a fluid-filled structure. (Courtesy Charles A. Whelan, MD, Montclair, NJ.)

Figure 56-43 Pseudomyxoma peritonei. **A.** Upper abdomen reveals ascites with a scalloped contour to the liver and spleen (arrows). **B.** Midabdomen reveals massive ascites with heterogeneous attenuated fluid and septations causing mass effect on adjacent bowel loops.

associated soft tissue components (Fig. 56-44) is strongly suggestive of a mucinous cystadenocarcinoma of the appendix.^{238,240} Perforation is present in approximately 46% of patients with mucinous cystadenocarcinoma at the time of appendectomy.²⁴¹ Patients with mucinous cystadenocarcinomas associated with pseudomyxoma peritonei have a poor 5-year survival rate of 50%.²⁰³

NONMUCINOUS ADENOCARCINOMA

Primary appendiceal adenocarcinoma is an uncommon tumor, with an incidence of approximately 0.08%.²⁴² Adenocarcinoma of the appendix presents as a soft tissue mass similar to the more

common colonic carcinoma, and it metastasizes hematogenously and lymphatically.

On CT examination, these tumors usually appear as a focal or diffuse soft tissue mass with appendiceal distention (diameter typically >15 mm), wall thickening, and associated soft tissue stranding of the periappendiceal fat (Figs. 56-45 and 56-46). When small, carcinoma of the appendix cannot be differentiated from complicated appendicitis.

Surgical treatment depends on the size and stage of the tumor. Small lesions without lymph node involvement can usually be treated with appendectomy, but more advanced appendiceal carcinoma typically necessitates right hemicolectomy.

Figure 56-44 Mucinous cystadenocarcinoma of the appendix. CT detects a mass having solid (s) and cystic (c) components in the right pelvis inferior and medial to the cecum (large arrows). Peripheral calcifications are seen in the cystic component (small arrows).

Figure 56-45 CT scan of perforated carcinoma of the appendix. A lobulated, heterogeneous complex mass (M) is seen posterior and caudal to the cecum. The mass has an irregular contour, and periappendiceal inflammatory changes are present (arrows).

Figure 56-46 CT scans of carcinoma of the distal appendix. A-C. Series axial CT scans of the right, mid, and lower abdomen show that a lobulated soft tissue mass (arrows) is present in the distal aspect of the appendix, with mural thickening identified in the more proximal appendix. Periappendiceal inflammatory changes are also identified (arrowheads).

CARCINOID

Carcinoid tumor is the most common neoplasm of the appendix, with an incidence of 0.32% in appendectomy specimens and 0.054% in an autopsy series.^{203,243} Appendiceal carcinoid tumors comprise 18.9% of all GI carcinoid tumors, but are less biologically aggressive than other GI carcinoid tumors.²⁴⁴ Most are smaller than 2 cm at presentation, and most patients

are asymptomatic. Typically, these lesions are incidentally found at surgery (Fig. 56-47). Appendiceal carcinoids have a lower average age at presentation (average, 42.2 years) than other GI carcinoid tumors (average, 62.9 years) or noncarcinoid appendiceal tumors (average, 61.9 years), have a tendency to present with coexistent tumors, have little metastatic potential, and have a female predominance (male-to-female ratio of 0.47).^{245,246} The 5-year survival for appendiceal

Figure 56-47 Carcinoid tumor of the appendix. An enhancing soft tissue mass (arrow) occludes the lumen of the appendix, which is dilated and fluid-filled (arrowheads). The patient presented with acute appendicitis.

carcinoids (85.9%) is higher than for other GI carcinoid tumors (54%).²⁴⁶

Most appendiceal carcinoid tumors ($\approx 70\%$) are located in the appendiceal tip, followed by the body (approximately 22%) and the base (approximately 7%).²⁰³ The typical CT appearance

is a homogeneous soft tissue mass that may infiltrate into the cecum and mesentery.²⁴⁷

Treatment of appendiceal carcinoid depends on its size. Tumors smaller than 2 cm are usually treated with appendectomy. Tumors larger than 2 cm or with evidence for invasion into the mesoappendix necessitate right hemicolectomy and, unfortunately, have a poorer prognosis.²⁰³

LYMPHOMA

Primary appendiceal lymphoma is a very rare lesion, with an incidence of 1% to 3%.^{248,249} Patients typically present with clinical signs mimicking those of acute appendicitis and with no prior history of lymphoma. At the time of diagnosis, most tumors are larger than 3 cm. All reported cases have been non-Hodgkin's type.²⁵⁰

On CT, there is usually marked mural thickening of the appendix, which maintains its vermiform shape. Aneurysmal luminal dilation may be present, and periappendiceal stranding may also be identified because of secondary appendicitis from luminal obstruction or direct serosal extension of lymphomatous cells.^{250,251}

Metastases

Primary neoplasms that can metastasize to the appendix include those of the breast, lung, bronchus, stomach, colon, pancreas, kidney, ovaries, or prostate. Direct extension of cecal or ileal tumors can also involve the appendix.²⁰³

Metastatic tumors of the appendix usually involve the serosal or submucosal layers and, on CT, they usually appear as a solitary soft tissue mass contiguous with the appendix. These lesions can obstruct the appendiceal lumen, leading to secondary appendicitis and its complications, including perforation.²⁰³

Differential Diagnosis of Colitis

Summary

The term *inflammatory bowel disease* encompasses two forms of chronic, idiopathic intestinal inflammation, ulcerative colitis and Crohn's disease. Although many other inflammatory diseases affect the gut, most are distinguished by a specific identifiable causative agent or process or by the nature of the inflammatory activity. The cause of ulcerative colitis and Crohn's disease is unknown, so these disorders are empirically defined by their typical pathologic, radiologic, clinical, endoscopic, and laboratory features.¹⁻⁷ This chapter summarizes the features that usually permit an operational distinction to be made between ulcerative colitis and Crohn's disease. The fundamental validity of this classification is uncertain and will remain so until the cause and pathogenesis of these disorders are better understood.

Ulcerative Colitis

Ulcerative colitis is a diffuse inflammatory disease of unknown origin that primarily involves the colorectal mucosa but later extends to other layers of the bowel wall. The disease characteristically begins in the rectum and extends proximally to involve part or all of the colon. The diagnosis is usually made on the basis of clinical symptoms and the presence of inflamed mucosa on sigmoidoscopy and confirmed by the findings on barium enema and mucosal biopsy.^{5,6}

HISTORICAL PERSPECTIVE

Although Hippocrates was aware that diarrhea was not a single disease, it required more than 2 millennia before ulcerative colitis was distinguished from the very common infectious enteritides. In 1859, Wilks described the case of Mrs. Isabella Banks, who had "inflammation of the large intestine" and was "affected by discharge of mucus and blood, where, after death, the whole internal surface of the colon presented a highly vascular soft, red surface covered with tenacious mucus, adherent lymph."⁸ By 1900, ulcerative colitis was fully characterized in terms of its clinical and pathologic criteria.¹

EPIDEMIOLOGY

Epidemiologic data have yielded some important clues concerning the cause of ulcerative colitis. The salient epidemiologic features of ulcerative colitis are listed in [Box 57-1](#) and will be discussed in more detail.

Ulcerative colitis is more common than Crohn's disease, with an annual incidence of 2 to 10 cases/100,000 population. The worldwide prevalence ranges from 35 to 100 cases/100,000 population. This wide range is probably the result of true differences in disease distribution as well as differences in reporting, diagnostic criteria, and availability of medical care.⁷ The incidence of ulcerative colitis has remained steady. This is in sharp contrast to Crohn's disease, which has shown a sixfold increase in incidence over the past 3 decades.

Ulcerative colitis is most prevalent in the developed countries of northern Europe, Scandinavia, British Isles, United States, and Israel. The incidence of ulcerative colitis in high-prevalence areas has leveled off, whereas the incidence of Crohn's disease has been increasing. In low-prevalence geographic areas, the incidence of ulcerative colitis has been increasing.⁷ Ulcerative colitis is four times more common in whites than in nonwhites, and there is a slight female preponderance.⁷

BOX 57-1 EPIDEMIOLOGY OF ULCERATIVE COLITIS

Worldwide prevalence: 35-100 cases/100,000 population
 Annual incidence: 2-10 cases/100,000 population
 Bimodal age distribution—peak, 15-25 yr; smaller peak, 50-80 yr
 Risk factors
 White (2-5× risk)
 Jewish (2-4× risk)
 Live in developed country
 Urban dweller
 Family history (30-100× risk)
 Sibling with disease (8.8% incidence)
 Single
 Nonsmoker

Adapted from Osterman MT, Lichtenstein GR: Ulcerative colitis. In Feldman M, Friedman LS, Branch LJ (eds): Gastrointestinal and Liver Disease, 8th ed. Philadelphia, Saunders, 2010, pp 1975-2090.

There is a twofold to fourfold increase of ulcerative colitis among Jews. The incidence of ulcerative colitis is much lower among Israeli than among American and European Jews. Furthermore, the incidence of disease is lower in Sephardic than in Ashkenazi Jews in Israel. These disparate rates suggest that a hereditary predisposition may be altered by environmental factors.⁷

The peak age at onset of ulcerative colitis is between 15 and 25 years of age, with a smaller peak at ages 55 to 65 years. Ulcerative colitis is more common than Crohn's disease in children younger than 10 years. Ulcerative colitis is more common in urban than in rural populations.⁷

The incidence of ulcerative colitis among first-degree relatives is 30 to 100 times greater than that of the general population.⁷ Of patients with ulcerative colitis, 10% to 20% have a similarly affected first-degree relative. The lifetime risk of developing ulcerative colitis among first-degree relatives is 8.9% for offspring, 8.8% for siblings, and 3.5% for parents. The child develops the disease at a much younger age than the affected parent—a phenomenon known as genetic anticipation. Familial ulcerative colitis seems to follow a polygenic inheritance pattern.⁷

The risk of developing ulcerative colitis for current smokers compared with lifetime nonsmokers is 59% less, but the risk is elevated by 64% for former smokers. However, smoking is not therapeutic, and there is no strong evidence of a beneficial effect of smoking on the clinical course of ulcerative colitis. Patients who quit smoking before the onset of disease have more frequent hospitalizations and colectomies. This fact raises the possibility that smoking cessation may lead to more severe illness.^{8,9}

The mortality rate of ulcerative colitis has significantly improved, which can be attributed to improvements in diagnosis and management. In the past, ulcerative colitis was responsible for 90% of deaths attributable to inflammatory bowel disease (IBD). More recently, the proportion of ulcerative colitis and Crohn's disease deaths is about equal—1/100,000 for those 20 to 29 years and 3 to 4/100,000 for those 50 to 59 years of age.⁷ Approximately 78% of ulcerative colitis patients die of causes unrelated to bowel disease. Colorectal cancer caused 14% of deaths in ulcerative colitis patients in one study.⁷

PATHOGENESIS AND CAUSATIVE FACTORS

Despite exhaustive work by many investigators, the cause of ulcerative colitis is still unknown. Although the participation of genetic, environmental, neural, hormonal, infectious, immunologic, and psychological factors in the pathogenesis of this disease is well established, none of the mechanisms has proved to be the primary causative agent. In addition, it now appears that distal ulcerative proctitis may have a cause different from that of pancolitis.¹⁻⁴

As noted, familial aggregation of ulcerative colitis is well recognized. The postulated mode of inheritance of susceptibility to ulcerative colitis is through polygenes. The disease occurs with greatest frequency in monozygotic twins. Human leukocyte antigen (HLA) phenotypes B5, Bw52, and DR2 also have a significant association with ulcerative colitis. Ulcerative colitis is often associated with the autoimmune disorders, sacroiliitis, ankylosing spondylitis, enteropathic oligoarthritis, and anterior uveitis, which are associated with HLA-B27 antigen.⁴⁻⁶ Possibly, genes related to ulcerative colitis may encode products that contribute to functional or structural abnormalities in the colon, which render it more susceptible to attack by infection, toxins, and autoimmune actions.⁸

Patients with ulcerative colitis have abnormal mucin production, which may permit various intraluminal bacterial products and toxins to attack the mucosa. It is uncertain whether this defect is a cause or effect of the disease.⁴⁻⁶ An infectious cause for IBD with a direct cause and effect relationship between a single microorganism and inflammation still remains plausible. *Chlamydia*, mycobacteria, gut anaerobes, cytomegalovirus, *Yersinia*, and bacterial cell wall components have all been implicated as a cause of ulcerative colitis. It is also possible that bacteria that normally constitute normal flora may be pathogenic in a susceptible host.⁴⁻⁶

In ulcerative colitis, the enteric nervous system and nerves containing substance P and vasoactive intestinal polypeptide (VIP) become straight, thick, and highly immunoreactive. Substance P and VIP are powerful mediators in neurogenically induced inflammation and cause vasodilation, plasma extravasation, and watery diarrhea. All these factors may have a role in the pathophysiology of IBD.⁴⁻⁶

The immune system provides an important contribution to the pathogenesis of ulcerative colitis because of failure to clear a microbial or toxic agent or because of an inappropriate response to it. The immune system probably mediates the tissue injury as well, regardless of the trigger, and this is the basis of therapy with corticosteroids and other immunosuppressive agents. The colonic inflammation of ulcerative colitis may merely be an exaggerated physiologic response that is always present within the lamina propria of the colon. There is an alteration of the relative representation of macrophages and T-cell and B-cell populations and an increase in the numbers of immunoglobulin G-bearing cells. The disease is also characterized by a fundamental alteration in antigen-presenting activity associated with a reduction of intestinal suppressor T cells and elevated levels of cytotoxic Leu-7-positive cells. Increased levels of specific antibodies to antigens in the gut lumen are also found.¹⁻⁶ These immunologic disturbances offer great potential for therapy with new immunosuppressive and biologic agents (see later).

Ulcerative colitis is a complex disease. It consists of interactions among initiating organisms or antigens, the host's immune

response, and immunologic, environmental, and hereditary influences.

FINDINGS

Clinical Findings

Ulcerative colitis is highly variable in clinical course, severity, and prognosis. Disease activity waxes and wanes and is characterized by acute exacerbations of bloody diarrhea that resolve spontaneously or after therapy. The most common clinical findings are diarrhea, abdominal pain, rectal bleeding, weight loss, and tenesmus; vomiting, fever, constipation, and arthralgias occur less commonly.¹⁰⁻¹²

Ulcerative colitis usually behaves as a chronic low-grade illness in most patients. In 15% of patients, this disease has an acute and fulminating course, with explosive diarrhea, hematochezia, and hypotension. Most patients (60%-75%) have intermittent attacks with complete symptomatic remission between attacks, 4% to 10% have one attack and no subsequent symptoms, and 5% to 15% are troubled by continuous symptoms without remission.^{10,11}

Patients with ulcerative proctitis have disease of mild severity, and the disease usually remains distal. There is extension to the proximal colon in 15% of patients over a 10-year period and extension to the hepatic flexure in 7%. At presentation, 30% of patients have disease limited to the rectum, 40% have disease extending above the rectum but not beyond the hepatic flexure, and the remaining 30% have pancolitis. Extraintestinal manifestations, such as arthralgias, mild arthritis, eye inflammation, and rash, are present in fewer than 10% of patients at initial presentation.^{1-5,10,11}

Physical examination discloses fever, prostration, dehydration, and postural hypotension in the most severe cases. The abdomen may be protuberant because of colonic atony and distention. Abdominal tenderness over the colon and absent bowel sounds are ominous signs suggesting toxic megacolon or early perforation. Patients with milder involvement present with pallor, low-grade fever, weight loss, and mild abdominal tenderness.^{10,11}

Endoscopic Findings

Sigmoidoscopy is helpful in establishing the diagnosis of ulcerative colitis because the distal colon and rectum are involved in 90% to 95% of cases. Early on, the mucosa is edematous and friable, with loss of the normal vascular pattern and bleeding when touched by the endoscope or rubbed with a cotton swab. With disease progression, granular, spontaneously hemorrhagic mucosa is found, associated with a mucopurulent exudate. The haustra are thick and blunted, the lumen seems narrowed and straightened, and the normal thin (<2 mm) mucosal folds are lost. In severe disease, the mucosa is diffusely hemorrhagic, and frank ulceration with loss of mucosal irregularity is seen.^{3,13,14}

Radiologic Findings

Plain Abdominal Radiographs. Considerable information can be gained by carefully scrutinizing the abdominal radiographs of patients with ulcerative colitis. Although attention should be focused on the colon, other abnormalities, such as renal calculi, sacroiliitis, ankylosing spondylitis, and avascular necrosis of the femoral heads, must also be excluded.¹⁵⁻²⁰

Although the extent of ulcerative colitis is generally determined by barium enema and colonoscopy, these procedures carry a higher risk in severely ill patients. The following radiographic features can be used to assess the severity and extent of the colitis: (1) the extent of formed fecal residue; (2) the appearance of the mucosal edge; (3) alterations of the haustra; (4) colonic width; and (5) mural thickness.¹⁵

Colonic Fecal Residue. The distal extent of formed fecal residue provides a good indication, although not absolute, of the proximal extent of the colitis (Fig. 57-1). This approach sometimes overestimates but does not underestimate the extent of disease. The following conclusions can be drawn from the extent of residue¹⁵⁻²³:

1. If no residue is visible, the patient probably has active pancolitis.
2. If the residue extends down into the sigmoid colon, proctitis is present (this may be indistinguishable from normal).

Figure 57-1 Ulcerative colitis: plain film estimation of active disease. The distal extent of fecal residue may overestimate but seldom underestimates the proximal extent of active disease. (From Bartram C, Kumar P: *Clinical Radiology in Gastroenterology*. Oxford, England, Blackwell Scientific, 1981, p 135.)

3. If residue is present only in the proximal colon, the colitis most likely extends to this level but could be more distal.

Mucosa. The colonic mucosal edge is normally smooth. In active colitis, the line is granular, indistinct, and somewhat fuzzy. With frank ulceration, the mucosal line is disrupted, which causes an irregular edge. With extensive ulceration, only edematous mucosal islands remain. Intramural, mottled-appearing gas shadows may be present in fulminating colitis with necrosis of the bowel wall. Linear pneumatosis suggests extremely deep ulceration or extraperitoneal perforation with gas trapped adjacent to the bowel wall.¹⁵⁻²³

Haustration. Normal haustral clefts run in parallel, about 2 to 4 mm apart, across one third of the diameter of the colon. Widening of the haustral clefts with loss of the parallel lines is an early manifestation of ulcerative colitis and is more obvious on radiographs than the mucosal granularity that it accompanies. The haustra may be completely absent as well. Blunting can be confused with underdistention, so it should not be diagnosed if only a small amount of gas is present within the colon.¹⁵⁻²³

Colon Diameter. The upper limit of normal for the diameter of the transverse colon is 5.5 cm. In chronic, “burned out” ulcerative colitis, the colon becomes tubular and narrowed and is considerably less than 5 cm in diameter. In these patients, if the colon is more than 5 cm in diameter, the inflammation has become transmural, which indicates a fulminant colitis at risk for perforation or toxic megacolon.¹⁵⁻²³

Mural Thickness. In the normal colon, the distance between the line of pericolic fat and gas-filled lumen is less than 3 mm. In chronic ulcerative colitis, it increases to more than 3 mm in thickness. In a study assessing these findings, a combination of four features was pathognomonic for disease proximal to the hepatic flexure: irregularity of the mucosal edge, loss of haustral clefts, increased thickness of the colon wall, and an empty right colon.¹⁹

Barium Enema

The barium enema has the following roles in patients with ulcerative colitis: (1) to confirm the clinical diagnosis; (2) to assess the extent and severity of disease; (3) to differentiate ulcerative colitis from Crohn’s disease and other colitides; (4) to follow the course of disease; and (5) to detect complications. The role of barium enema has largely been supplanted by colonoscopy, multidetector computed tomography (MDCT),

and magnetic resonance imaging (MRI) in patients with ulcerative colitis. The major radiographic findings on the barium enema examination in ulcerative colitis are presented in [Box 57-2](#); their anatomic and pathologic origin ([Fig. 57-2](#)) and significance are discussed subsequently.

Granular Pattern. The earliest pathologic changes of ulcerative colitis are hyperemia and the accumulation of inflammatory cells in the mucosa.^{24,25} These changes are manifested by a loss of normal mucosal translucency and obscuration of the submucosal pattern on endoscopy.^{26,27} Subtle thickening of the mucosa or haustral edema may be present radiographically, but these findings are often appreciated only in retrospect.²⁶ With progressive edema and hyperemia, the mucosa develops a granular pattern ([Fig. 57-3A](#)).²⁷⁻²⁹ The smooth, sharp, and distinct appearance of the colonic margin seen on normal double-contrast studies is replaced by an amorphous, thickened, and indistinct mucosal line. There is a gradual transition between the normal and abnormal mucosa that extends for several centimeters. This granularity should be distinguished from the granular appearance of chronic ulcerative colitis (see [Fig. 57-3B](#)). In chronic ulcerative colitis, the mucosal surface pattern is coarser, and there are significant changes in colonic contour.

The granular pattern develops as a result of abnormalities in the quality and quantity of mucus produced by the involved

BOX 57-2 ULCERATIVE COLITIS: BARIUM ENEMA FINDINGS

ACUTE CHANGES

- Mucosal granularity
- Mucosal stippling
- Collar button ulcers
- Haustral thickening or loss
- Inflammatory polyps
- Confluent, contiguous, circumferential disease

CHRONIC CHANGES

- Haustral loss
- Luminal narrowing
- Loss of rectal valves
- Widened presacral space
- Backwash ileitis
- Postinflammatory pseudopolyps

Figure 57-2 Spectrum of mucosal abnormalities in ulcerative colitis. 1, Punctate mucosal ulcer-crypt abscess; 2, collar button ulcer; 3, polypoid accumulation of granulation tissue; 4, mucosal remnant forming inflammatory pseudopolyp; 5 and 6, sessile mucosal polyps (similar morphologic features are seen in hyperplasia, adenoma, and carcinoma); 7, pedunculated polyp (typically hyperplastic or low-grade adenomas); 8, 9, and 10, postinflammatory pseudopolyps of various configurations; 11, mucosal remnant bridging area of active undermining ulceration; 12, mucosal bridge in quiescent state with previously denuded surfaces covered with new epithelium. (From Lichtenstein JE: Radiologic-pathologic correlation of inflammatory bowel disease. *Radiol Clin North Am* 25:324, 1987.)

Figure 57-3 Ulcerative colitis: granular mucosal pattern. **A.** Early ulcerative colitis. The blunted haustral clefts are evident on this spot image of the sigmoid colon. The mucosal granularity, attributable to abnormal quantity and quality of mucin, is contiguous, circumferential, and symmetric. **B.** Chronic ulcerative colitis. This spot image of a short, tubular, ahaustral splenic flexure of the colon shows a coarser surface pattern than that seen in acute disease.

mucosa.²⁵ On histologic examination, there is a reduction in the number of goblet cells, which contain less than the normal complement of mucin.^{6,25,30,31} Normal mucus is essential to normal barium coating of the gut. Any process, whether benign or malignant, infectious or inflammatory, that alters mucin production affects mucosal coating and visualization.²⁵

Mucosal Stippling. During the granular phase of ulcerative colitis, inflammatory cells accumulate at the base of the mucosal crypts.^{25,31} Cellular debris tends to block the crypts of Lieberkühn, which leads to the formation of microabscesses, better known as crypt abscesses (Fig. 57-4A). These crypt abscesses eventually erode into the lumen.^{30,31} The ulcers deepen, and barium flecks become adherent to them, producing mucosal stippling (see Fig. 57-4B).²⁵ This stippling resembles white paint applied by dabbing a surface with the end of a fairly dry paintbrush.²⁷

“Collar Button” Ulcers. With disease progression, the ulcers of the crypt abscess breach the lamina propria and muscularis mucosae and cause undermining of the less resistant areolar tissue of the submucosa.³⁰ The involved submucosa becomes necrotic, and the ulcers extend laterally, causing further undermining. This undermining is contained by the muscularis propria on the serosal side and by the muscularis mucosae on the luminal side of the colon.^{32,33} The ulcers are frequently related to the taeniae. The mucosal defect is small relative to the degree of undermining and produces a flasklike, so-called collar button ulcer (Fig. 57-5).²⁵ As these ulcers enlarge and interconnect, the collar button ulcer configuration is lost; a network of residual islands of mucosa and inflammatory pseudopolyps is produced.

Polyps. A variety of different mucosal protrusions may be seen on barium studies in patients with IBD.²⁵ Their appearance and significance depend on the stage of disease and pathologic origin.

Inflammatory Pseudopolyps. In patients with severe ulcerative colitis, there is extensive mucosal and submucosal ulceration in which only small islands of mucosa and submucosa may survive. The inflamed edematous mucosa protrudes above the surrounding areas of ulceration, which gives a polypoid appearance (Fig. 57-6).³¹ Because these represent merely the remnants of preexisting mucosa and submucosa rather than new growths, they are termed *pseudopolyps*.³¹ Inflammatory pseudopolyps are the natural progression of collar button ulcers: the ulcers extend and interconnect so that the pseudopolyp rather than the ulcers becomes the major radiographic finding.³⁴⁻³⁸ Inflammatory pseudopolyps usually occur in ulcerative colitis but may also be seen in Crohn’s disease. The cobblestoning pattern seen in Crohn’s disease is another type of pseudopolyp, in which larger islands of preserved mucosa are surrounded by linear and transverse ulcerations.²⁵

Postinflammatory Pseudopolyps. When IBD goes into remission, the denuded mucosa heals and is covered by granulation tissue that has a granular appearance similar to that observed in the early stages of ulcerative colitis.^{6,31,36-38} In some patients, the regenerated mucosa has a tendency to overgrow (Fig. 57-7). This overgrowth often results in polypoid lesions that may be small and rounded, long and filiform, or proliferate into a bushlike structure simulating a villous adenoma. Because the regenerating mucosa is cytologically normal, it is not a true neoplasm but a pseudopolyp. Because this occurs during mucosal healing, it is termed a *postinflammatory pseudopolyp*.³⁴⁻³⁸ These polyps represent the aftermath of a severe attack of colitis

Figure 57-4 Ulcerative colitis: crypt abscess causing mucosal stippling. **A.** A crypt abscess (arrow) is seen at the base of a crypt of Lieberkühn. **B.** When these abscesses erode into the lumen, they accumulate punctate collections of barium, which produces mucosal stippling.

Figure 57-5 Ulcerative colitis: collar button ulcers. **A.** Narrow neck of the crypt abscess erodes through the muscularis mucosae into the submucosa. The ulcer spreads laterally through the submucosa and is contained with a flat base by the resistant inner circular layer of the muscularis propria. **B.** Low-power photomicrograph shows characteristic undermining with a flat base (arrows). **C.** Spot film of the splenic flexure shows multiple flasklike ulcers (arrows) with a flat base. The ulceration is limited to the layers superficial to the muscularis propria. (A from Lichtenstein JE: Radiologic-pathologic correlation of inflammatory bowel disease. *Radiol Clin North Am* 25:324, 1987.)

Figure 57-6 Ulcerative colitis: inflammatory pseudopolyps. **A.** Inflammatory pseudopolyps (arrow) are identified on a double-contrast barium enema study. These pseudopolyps are seen when extensive mucosal and submucosal ulcerations leave only small residual islands of surviving mucosa and submucosa. Thus, they represent remnants of preexisting mucosa and submucosa rather than new growths. **B.** Intraoperative image of a diseased colon showing multiple residual islands of whitish mucosa surrounded by hemorrhagic ulcerations.

and may be the only sign of previous disease. Mucosal bridges are also postinflammatory pseudopolyps, in which a bridge of mucosa survives between islands of mucosa surrounded by ulceration. With remission, the underside of the mucosal bridge and underlying ulcer re-epithelialize.^{39,40}

Postinflammatory pseudopolyps can also be seen after ischemia, after severe infection, and in Crohn's disease. Filiform polyps have also been described in the esophagus, stomach, and small bowel in patients with Crohn's disease.²⁵

Backwash Ileitis. In 10% to 40% of patients with chronic ulcerative pancolitis, the distal 5 to 25 cm of ileum is inflamed (Fig. 57-8). This ileitis occurs only in the presence of pancolitis and usually resolves 1 to 2 weeks after colectomy.^{15,26} Although small ulcerations may be present, this is not a primary inflammation of the ileum. The distal ileum can be used to form an ileostomy or pouch. The pathogenesis of this disorder is uncertain but may relate to the reflux of colonic contents into the small bowel, hence the term *reflux* or *backwash ileitis*.¹⁵

Barium studies reveal a chronic pancolitis associated with a patulous and fixed ileocecal valve that easily refluxes and persistent dilation of the terminal ileum. The normal fold pattern is absent, and the mucosa is granular.

Blunting and Lost Haustra. In the course of ulcerative colitis, the haustral folds undergo two major changes (Fig. 57-9; see also Fig. 57-8): (1) early in the disease, they are edematous and thickened; (2) with chronic disease, they become blunted or may be completely lost.¹⁵ This evolution of haustral changes can be understood by a brief review of haustral formation.

At birth, colonic haustra are usually absent, which explains why it is difficult to differentiate colonic from small bowel gas in neonates. As the colon grows, the circular muscle of the muscularis propria outgrows the longitudinal muscle, the taenia coli. This differential growth rate causes the taeniae to shorten the colon in an accordion-like fashion, with production of saccular haustra that usually are first seen by the age of 3 years.⁴¹

Haustra are fixed anatomic landmarks in the proximal colon because the circular muscle is fused to the taeniae. In the distal colon, haustra are created by active contraction of the taeniae. Consequently, the colon can normally be devoid of haustra distal to the midtransverse colon; loss of haustra in the proximal colon is always abnormal.^{41,42}

In early ulcerative colitis, the haustra are deformed and thickened because of edema and may produce a corrugate outline to the colon, which has been called the indenture sign.⁴³ In chronic ulcerative colitis, the haustra are often lost for two reasons, alterations in the muscle tone of the taeniae^{41,42} and the fact that the colon is shortened. In this disease, the taeniae coli become relaxed for some unknown reason. This relaxation is associated with abolition of the haustral pattern. With healing, the haustra may reappear as they gain tone. A second major factor is also at work in chronic ulcerative colitis—massive hypertrophy and fixed contraction of the muscularis mucosae (Fig. 57-10), which causes foreshortening of the colon. Thus, the normal accordion-like array of colon on the relatively shorter taeniae is lost.⁴²⁻⁴⁵

Widened Presacral Space. When the rectum is distended, the retrorectal space as projected on true lateral films obtained during barium enema is usually 7.5 mm or less.⁴⁶ A distance of 1 to 1.5 cm is considered a moderate increase of this space, and a distance greater than 1.5 cm is abnormal. These values are obtained by measuring the shortest distance between the posterior edge of the barium column and the anterior edge of the second sacral segment. The presacral space is frequently widened in chronic ulcerative colitis and Crohn's disease but may also be seen in obese patients and patients with pelvic lipomatosis, pelvic carcinomatosis, radiation fibrosis, inferior vena cava thrombosis, sacral and rectal tumors, chlamydial infection, and other infectious proctitides.⁴⁷⁻⁴⁹

In patients with ulcerative colitis, two processes account for the abnormal presacral space (see Fig. 57-10): (1) narrowing of the rectal lumen and its associated mural thickening; and (2) proliferation, inflammation, and infiltration of perirectal

Figure 57-7 Ulcerative and Crohn's colitis: postinflammatory pseudopolyps. **A.** These pseudopolyps are a manifestation of mucosal healing in which normal tissue elements overgrow. Lesions may be small and round or long and filiform. **B.** Both rounded and filiform pseudopolyps are seen in the sigmoid colon. **C.** Giant postinflammatory pseudopolyp of the splenic flexure in a patient with Crohn's colitis. Note the mucosal bridges (arrows).

Figure 57-8 Ulcerative colitis: backwash ileitis. **A.** Backwash ileitis (arrow) is demonstrated in this patient with chronic ulcerative pancolitis. **B.** In a different patient, note the patulous ileocecal valve, the dilated, granular-appearing terminal ileum, and the tubular, anastomotic colon.

Figure 57-9 Acute ulcerative colitis: loss of haustra. Haustra distal to the hepatic flexure are absent, and the taeniae coli are relaxed. The mucosa is granular in appearance. The colon is not shortened at this point because thickening and contraction of the muscularis mucosae have not yet developed at this early stage of disease.

fat. These changes are well demonstrated by CT and correlate with the edematous adipose tissue and enlarged perirectal lymph nodes that are commonly observed at the time of abdominoperineal resection in patients with ulcerative colitis. In patients with Crohn's disease, perirectal abscesses may also contribute to this widening.⁵⁰

Rectal Valve Abnormalities. At least one rectal valve should be visible on lateral rectal views of double-contrast enemas. The fold is usually seen at the level of S3 and S4 and should be less than 5 mm thick. The rectal valves are an important indicator of proctitis and should be interpreted with the size of the presacral space. Two situations are indicative of proctitis:

1. The presacral space is more than 1.5 cm, with the valve thicker than 6.5 mm or absent.
2. The presacral space is normal, but the valve thickness is more than 6.5 mm.

Absence of the rectal valves in the presence of a normal presacral space can be a normal variant.¹⁵

Strictures. Benign strictures are local sequelae of ulcerative colitis that occur in approximately 10% of patients.¹⁵ They are usually localized and smoothly tapering and are only rarely sufficiently narrow to cause obstruction. They are sometimes reversible and are usually found in the distal colon. Strictures that are not reversible and are located more proximally in the colon should be viewed with suspicion for a neoplasm. The strictures have been attributed to the changes of the muscularis

mucosae described earlier and are almost invariably associated with mural thickening on cross-sectional imaging.⁵¹⁻⁵⁵

Distribution. Ulcerative colitis originates in the rectum and extends proximally in a continuous fashion. There is often a fairly sharply defined margin between diseased and normal bowel. The affected mucosa is diffusely, contiguously, confluent, circumferentially, and symmetrically involved, without normal intervening mucosa. The rectum is almost invariably involved but may be spared in patients treated with corticosteroid enemas.

Computed Tomography

The subtle mucosal abnormalities that characterize the early stages of ulcerative colitis are beneath the spatial resolution of CT. With progressive disease, severe mucosal ulceration can denude certain portions of the colonic wall, leading to inflammatory pseudopolyps (Fig. 57-11).⁵⁶ When sufficiently large, these pseudopolyps can be visualized on CT. Mural thinning, unsuspected perforations, and pneumatosis can be detected on CT in patients with toxic megacolon.⁵⁷ In this regard, CT can be quite helpful in determining the urgency of surgery in patients with stable abdominal radiographs but a deteriorating clinical course. Postinflammatory pseudopolyps can also be seen on CT.

Mural thickening and luminal narrowing are common CT features of subacute and chronic ulcerative colitis (Fig. 57-12; Box 57-3). The mucosa becomes thickened because of hypertrophy of the muscularis mucosae in chronic ulcerative colitis. Also, the lamina propria is thickened because of round cell infiltration in acute and chronic ulcerative colitis. The submucosa becomes thickened because of the deposition of fat or, in acute and subacute cases, edema. Submucosal thickening further contributes to luminal narrowing.⁵⁸⁻⁶²

On CT, these mural changes produce a target or halo appearance when axially imaged. The lumen is surrounded by a ring of soft tissue density (mucosa, lamina propria, hypertrophied muscularis mucosae), surrounded by a low-density ring (edema or fatty infiltration of the submucosa), which in turn is surrounded by a ring of soft tissue density (muscularis propria).⁵⁸⁻⁶⁴ This mural stratification is not specific and can also be seen in patients with Crohn's disease, infectious enterocolitis, pseudomembranous colitis, ischemic and radiation enterocolitis, mesenteric venous thrombosis, bowel edema, and graft-versus-host disease.⁵⁸⁻⁶⁴

Rectal narrowing and widening of the presacral space are radiologic hallmarks of chronic ulcerative colitis.⁶⁵⁻⁶⁸ MDCT depicts the anatomic alterations that underlie these rather dramatic morphologic changes (see Fig. 57-10). The rectal lumen is narrowed because of the mural thickening that attends chronic ulcerative colitis (see earlier). As a result, the rectum has a target appearance on axial scans, which should not be mistaken for the external anal sphincter, mucosal prolapse, or levator ani muscles. The increase in the presacral space is caused by proliferation of the perirectal fat.

Ultrasonography

IBD alters the thickness and echogenicity of the gut wall or individual layers, integrity of mural stratification, appearance of surrounding tissues, and bowel motility and compressibility (Box 57-4).⁶⁹⁻⁷⁴ Edema is a prominent feature of acute intestinal inflammation. Edema results in thickening of the colon wall and preservation of wall stratification (Fig. 57-13). On

Figure 57-10 Cause of rectal contour changes in chronic ulcerative colitis. **A.** Marked hypertrophy of the muscularis mucosae. This muscle, oriented along the long axis of the colon, is chronically contracted, even after the IV administration of glucagon and in formalin-impregnated specimens. This contraction shortens and narrows the involved colon. The submucosa also widens and shows various degrees of fatty infiltration, further narrowing the lumen. The taeniae coli are relaxed, which abolishes the haustral folds. **B.** Pelvic CT scan shows a characteristic target or ring sign with a thickened, low-density submucosa (arrow) caused by fatty infiltration. The soft tissue density ring on the lumen side of the submucosa represents thickened lamina propria and muscularis mucosae; the ring on the serosal side is muscularis propria. **C.** Corresponding lateral view from an air-contrast barium enema. The mucosa has a granular appearance, the lumen is narrowed, the valves of Houston are absent, and there is significant widening of the presacral space (double arrow). (A from Gore RM: Colonic contour changes in chronic ulcerative colitis: Reappraisal of some old concepts. *AJR* 158:59–61, 1992.)

transverse section, alternate hyperechoic and hypoechoic layers give rise to a target appearance. In ulcerative colitis, the mucosa becomes thickened and hypoechoic as a result of edema.^{73,74} The submucosa also thickens, but colonic motility is maintained. With progressive disease, haustral septations are lost. In patients with well-established disease, bowel wall thickness is approximately 0.6 ± 0.2 cm.⁶²⁻⁶⁷ In one series, these changes were seen in all patients with pancolitis, in 94% of those with left-sided colitis, but in only 50% of patients with rectosigmoiditis. If there is extensive pseudopolypoidosis, the thickness of the wall may increase to 1.5 cm, which is often accompanied by loss of wall stratification.⁶⁸⁻⁷⁴

Magnetic Resonance Imaging

Magnetic resonance imaging is capable of identifying the mural stratification present in ulcerative colitis (Figs. 57-14 and 57-15). MRI demonstrates thickening and abnormal hypointensity of the mucosal and submucosal layers on T1- and T2-weighted images. The T1 shortening probably relates to the severe hemorrhagic phenomena that frequently appear in these layers. The degree of mural enhancement correlates well with the severity of disease activity on fat-suppressed gradient-echo images after the intravenous (IV) administration of gadolinium.⁷⁵⁻⁷⁹

Figure 57-11 Mucosal disease in acute ulcerative colitis: CT features. **A.** Pelvic CT reveals diffuse mucosal thickening of fluid-filled rectum and sigmoid. Deep ulcerations (arrows) are visualized. Note normal lumen caliber and ascites. **B.** Magnified CT image of distal descending colon shows residual islands of inflamed mucosa protruding above the denuded colonic surface, so-called inflammatory pseudopolyps (arrows). (From Gore RM, Balthazar E, Ghahremani GG, et al: CT features of ulcerative colitis and Crohn's disease. *AJR* 167:3–15, 1996.)

Figure 57-12 Subacute ulcerative colitis: CT features. Coronal reformatted image through the rectosigmoid reveals diffusely inflamed and thickened mucosa (arrow). The edematous submucosal layer of low attenuation is paralleled by the external layer of muscularis propria and the internal layer of submucosa, both of which have a higher attenuation.

BOX 57-3 ULCERATIVE COLITIS VERSUS CROHN'S DISEASE: COMPUTED TOMOGRAPHY FINDINGS

ULCERATIVE COLITIS

- Mural thickening <1.5 cm
- Target appearance of wall—submucosal edema (acute)
- Target appearance of wall—submucosal fat (chronic)
- Increased perirectal and presacral fat

CROHN'S DISEASE

- Mural thickening >2 cm
- Target appearance of wall—submucosal edema (acute)
- Target appearance of wall—submucosal fat (chronic)
- Homogeneous CT density of wall
- Mural thickening of small bowel
- Abscesses, fistulas, sinus tracts
- Mesenteric changes (abscess, phlegmon, fibrofatty proliferation)
- Perianal disease

COMMON FINDINGS

- Mural thickening
- Narrowed lumen
- Increased lymph node size and number

BOX 57-4 ULCERATIVE COLITIS VERSUS CROHN'S COLITIS: SONOGRAPHIC FINDINGS**ULCERATIVE COLITIS**

Moderately thick, hypoechoic wall
 Typical wall stratification maintained
 Loss of haustration
 Absent peristaltic motion

CROHN'S COLITIS

Clearly thickened, hypoechoic wall
 Loss of typical wall stratification
 Loss of haustration
 Diminished compressibility
 Absent peristaltic motion
 Increased blood flow of superior mesenteric artery with decreased resistive index

Figure 57-13 Chronic ulcerative colitis: sonographic findings. The descending colon, imaged longitudinally, shows circumferential mural thickening (arrows).

Scintigraphy

Although the diagnosis and assessment of disease activity of ulcerative colitis are made primarily by radiographic and endoscopic techniques, both gallium 67 (^{67}Ga) citrate and indium 111 (^{111}In)-labeled leukocyte scans have proved helpful for patients with IBD. Scintigraphic techniques are useful when there is danger of bowel perforation and the extent and degree of disease activity must be assessed. Positron emission tomography (PET) using ^{18}F -fluorodeoxyglucose (FDG) can also be used to assess disease activity. FDG uptake (Fig. 57-16)

Figure 57-15 Ulcerative colitis: MR features. T1-weighted MR coronal image shows loss of haustration and hyperenhancement of mucosa of the left colon (arrow) in this patient with active ulcerative colitis. (Courtesy Shahid M. Hussain, MD.)

Figure 57-14 Ulcerative colitis: MR findings. T1-weighted axial MR images of the rectum (A) and rectosigmoid junction (B) show mural thickening of the colon, submucosal fat deposition, increased presacral fat, and prominent vessels in the mesorectal fat.

Figure 57-16 Ulcerative colitis: positron emission tomography scanning features. Diffuse increased FDG uptake in the colon is present in this patient with acute, active disease.

is increased in areas of active inflammation resulting from hyperemia and increased metabolic activity.⁸⁰⁻⁸⁴

THERAPY

Medical Management

The treatment of ulcerative colitis depends on the severity, extent, and distribution of disease. Sulfasalazine, a congener of 5-aminosalicylic acid and sulfapyridine, is effective in the treatment of acute ulcerative colitis and in reducing the frequency and severity of recurrent attacks.⁸⁵ Sulfasalazine attenuates the bowel inflammation by a number of actions: (1) reduces production of prostaglandins; (2) diminishes leukotriene production, which activates neutrophils and other constituents of the inflammatory response; (3) blocks the chemotactic activity of formulated bacterial peptides that help recruit neutrophils to the bowel; and (4) acts as a scavenger of oxygen free radicals.⁸⁵ Many patients develop hypersensitivity or less specific forms of intolerance; efforts are now being made to deliver the active component, 5-aminosalicylic acid, without the sulfapyridine moiety, which apparently causes the hypersensitivity.⁸⁵

Corticosteroids are effective in patients with moderate to severe ulcerative colitis. They do not affect the rate or timing of disease recurrence in patients in remission. Topical hydrocortisone in the form of a foam enema is the mainstay of therapy for distal proctocolitis.⁸⁵

Azathioprine, 6-mercaptopurine, chloroquine, hydroxychloroquine sulfate (Plaquenil), methotrexate, and cyclosporine are alternative therapies in patients with refractory disease. Bowel

rest and nutritional therapy also have beneficial effects on this disease.⁸⁵

Increased concentrations of leukotrienes in the inflamed mucosa in ulcerative colitis have suggested the use of inhibitors of leukotriene B₄ (LTB₄) for therapy because this is a highly potent mediator of inflammation. LTB₄ receptor antagonists are under investigation as are inhibitors of platelet-activating factor and mast cell stabilizers.⁸⁵⁻⁸⁷

Anti-tumor necrosis factor (TNF) agents such as Remicade and Humira suppress part of the inflammatory response of IBD. Although used more commonly in patients with Crohn's disease, these agents have been found useful for patients with ulcerative colitis.

Surgery

Although proctocolectomy is always curative for ulcerative colitis, this procedure carries an operative risk, and not all patients are willing to accept an ileostomy. Consequently, colectomy is not indicated for patients who are easily managed medically. There are several major indications for surgery in ulcerative colitis: (1) massive, unremitting colonic hemorrhage; (2) toxic megacolon with impending or frank perforation; (3) fulminant colitis that is unresponsive to antibiotic, supportive immunosuppressive therapy; (4) obstruction from a stricture; and (5) suspicion or demonstration of colon cancer. Less immediate and definite indications for colectomy are (1) intractable chronic disease that becomes a physical and social burden to the patient and is unresponsive to appropriate therapy, (2) failure of children to mature at an acceptable rate, and (3) high-grade dysplasia in a patient with pancolitis.⁸⁸ Fulminant acute disease accounts for 13% to 25% of colectomies in patients with ulcerative colitis. Many of the extraintestinal complications of ulcerative colitis, such as uveitis and pyoderma gangrenosum, are also eliminated by colectomy. However, the course of hepatobiliary disease and ankylosing spondylitis is usually not altered by surgery.⁸⁸⁻⁹⁰ Since the 1980s, tremendous advances have been made in the surgical approach to ulcerative colitis that offer the patient and surgeon a variety of options.

Proctocolectomy with a Brooke Ileostomy. After a proctocolectomy is performed, the end of the ileum is passed through an opening in the middle aspect of the right rectus muscle at a point beneath the umbilicus that allows convenient placement of the forepiece of an ileostomy bag. This procedure is curative and requires one operation, but the patient must constantly wear an external ileostomy appliance that needs to be emptied four to eight times per day. Perineal wound problems, stoma revision, and small bowel obstruction occur in 10% to 25% of patients. This is the fastest and safest operation, but it dramatically alters body image in many patients, particularly younger ones.⁸⁸⁻⁹⁰

Proctocolectomy with Continent Ileostomy (Kock Pouch). A continent ileostomy is made by creating a pouch out of terminal ileum to hold the intestinal contents, an ileal conduit that leads from the pouch to the stoma, and an intervening intestinal valve. Patients empty the pouch by passing a tube through the valve via the stoma. The ileostomy is continent, so an external appliance is not needed. The nipple valve is created by intussuscepting the terminal ileum in a retrograde manner into the pouch for 3 to 4 cm. Anatomic complications requiring reoperation develop in 40% to 50% of these patients.⁹¹⁻⁹⁵

Figure 57-17 Surgical management of ulcerative colitis ileal pouch-anal anastomosis. **A.** The two-loop ileal J pouch shown in the intraoperative image is simple to construct, provides adequate storage capacity, and is evacuated spontaneously and fully. **B.** Barium enema evaluation of such a pouch.

Total Colectomy with Ileorectal Anastomosis. Total colectomy with ileorectal anastomosis is no longer popular because of a fairly high complication rate and unpredictable functional result.⁹¹⁻⁹⁵

Total Proctocolectomy, Rectal Mucosal Stripping, and Ileal Pouch Formation with Anastomosis to the Sphincter. This is the preferred operation in most patients. An abdominal colectomy and mucosal proctectomy are performed. A J pouch or W-shaped pouch is fashioned out of ileum. This reservoir is then anastomosed to the anus (Fig. 57-17). The endorectal ileal pouch and anal anastomosis are given 8 weeks to heal by diverting the gut through a conventional ileostomy.⁹⁰⁻⁹⁵ The advantages of this procedure are that no stoma is required and that fecal continence is usually maintained, albeit with bowel movements four to eight times per day.

This procedure is technically demanding and requires two operations. Complications include postoperative abscess, pouch fistulas, stenosis, small bowel obstruction, and pouchitis. Approximately 15% of patients require reoperation, and some ultimately require a conventional ileostomy. Pouchitis is an inflammatory process that can cause tenesmus, bloody diarrhea, and constitutional symptoms similar to those of ulcerative colitis.⁹⁵⁻¹⁰⁰

PROGNOSIS

The prognosis in ulcerative colitis has improved dramatically. Most patients have mild to moderate disease, and only 15% to 25% require a colectomy. Mortality associated with ulcerative colitis occurs in the first 2 years of disease, primarily in patients older than 40 years—one third attributable to the colonic disease itself, one third caused by complications of the disease (colorectal cancer, sclerosing cholangitis, thromboembolic disease, medical and surgical therapy), and the remaining third attributable to unrelated causes. Excess mortality of 2.1% for men and 1.5% for women has been reported, but only for the

first 2 years of disease.¹⁰ Most patients with ulcerative colitis can cope with their disease and achieve what is subjectively interpreted as a relatively acceptable lifestyle.¹⁰

Crohn's Disease

Crohn's disease is a chronic, cicatrizing disorder of the alimentary tract characterized by granulomatous inflammation of the mucosa, bowel wall, and surrounding mesentery. Any portion of the alimentary tract may be involved, but the terminal ileum and proximal colon are most frequently diseased.^{2,4,6}

HISTORICAL PERSPECTIVE

It is difficult to decide who described the first case of "regional ileitis" or "ileocolitis."¹ In 1806, Combe and Saunders described "a singular case of stricture and thickening of the ileum." Although similar cases were reported in the 19th century and early years of the 20th century, the first series of satisfactorily documented cases of regional enteritis was described by Crohn, Ginzburg, and Oppenheimer in 1932 at Mount Sinai Hospital in New York.^{2,4,6} Crohn's disease was originally called *terminal ileitis* because these cases were located mainly in the distal ileum in young persons. The outstanding complaints of the patients were diarrhea and weight loss, with progressive anemia and fever. Pathologic examination showed a thickened intestinal wall with subacute or chronic necrotizing inflammation and a greatly enlarged mesentery. Small linear ulcerations with distorted and broken mucosal folds and a cobblestone appearance were noted. The ulceration of the mucosa was accompanied by a disproportionate connective tissue reaction in the bowel wall, leading to stenosis and multiple fistulas. The lumen was "irregularly encroached" with dilation of proximal areas of the bowel.^{2,4,6,101,102} Many years later, it was realized that Crohn's disease might be confined to the colon without affecting the ileum; it is now recognized that Crohn's disease can involve every portion of the gut, from the mouth to the anus.^{2,4,6}

PATHOGENESIS AND CAUSATIVE FACTORS

The cause of Crohn's disease remains unknown. Although the participation of genetic, environmental, infectious, immunologic, and psychologic factors in the pathogenesis is well established, none of these mechanisms has proved to be the primary causative agent.¹⁰² Genetic vulnerability is likely to facilitate the occurrence of the disease, whereas the other factors may play a supportive and superimposed role. A further complicating factor in establishing a cause is the fact that in practice, Crohn's disease does not behave as a single disorder.^{6,11}

More recently, interest has centered on immunologic mechanisms, in particular the role of platelet-activating factor. Platelet-activating factor is a form of phosphatidylcholine that causes inflammation that is detectable in colonic mucosa in IBD but is not present in normal colonic mucosa. Production of platelet-activating factor is stimulated by a number of inflammatory mediators, such as prostaglandin and leukotrienes. In vitro studies have demonstrated that levels of several forms of prostaglandin are significantly elevated in the mucosa in Crohn's colitis and ulcerative colitis. Local release of LTB₄ by the rectal mucosa is considerably increased in ulcerative colitis but is elevated in Crohn's colitis only when frank ulceration is present.^{2,4,6,11} Consequently, safe inhibitors of platelet-activating factor are now being sought, which could prove to be a powerful new form of therapy.

Other immunologic evidence suggests that there is a failure of suppressor cell generation coupled with a hyperactive state of helper T cells in patients with IBD. The activated T cells may then lead to an overactive immune response that is not turned off. This response results in increased macrophage activation, enhanced cytokine production, and augmented antibody secretion. Although immunologic factors are important, no specific antibody-producing antigen has been identified in the intestinal mucosa of patients with IBD. Also, there is still no convincing demonstration of any fundamental underlying immune defect. Further evidence against immunodeficiency as the cause of Crohn's disease comes from the report of a patient who had a prolonged remission coincidental with acquiring human immunodeficiency virus (HIV) infection. Similarly, exhaustive efforts to relate mycobacterial infection to Crohn's disease have been unsuccessful. A defect in mucosal permeability that permits absorption of macromolecules and complex sugars may be another important factor in the pathophysiology of Crohn's disease. Apparently healthy relatives of patients with Crohn's disease show the same intestinal permeability defect. This finding suggests that this defect may antedate intestinal inflammation and may also play a causative role.^{2,4,6,11}

EPIDEMIOLOGY

Although understanding of the epidemiology of Crohn's disease is unclear, investigators hope that more precise information will yield important clues about cause.¹¹ Salient epidemiologic features are listed in [Box 57-5](#).

Crohn's disease is an uncommon but not rare disease, with a reported incidence between 0.6 and 6.3 cases/100,000 population. Worldwide prevalence ranges from 10 to 70 cases/100,000 population; this wide variation is probably because of actual differences in disease distribution, as well as differences in

BOX 57-5 EPIDEMIOLOGY OF CROHN'S DISEASE

Worldwide prevalence: 10-70 cases/100,000 population
 Annual incidence: 0.6-6.3 cases/100,000 population*
 Bimodal age distribution: Peak at 15-25 yr; smaller peak at 50-80 yr
 Risk factors
 White race
 Jewish (eightfold increase)
 Residence in urban area
 Family history of disease
 Sibling with disease (30-fold increase)
 Single
 Oral contraceptive use
 Smoking (fourfold increase)

*Incidence has increased 1.4 to 4 times in past 40 years.

reporting, diagnostic criteria, and availability of medical care.^{2,4,7}

Crohn's disease is most common in the developed countries of Europe and Scandinavia, United States, and Israel. The incidence is lower in Southern and Eastern Europe and the former Soviet Union. The disease is uncommon in Central and South America and Cuba and is rare in Asia and Africa. Crohn's disease has been increasing in incidence over the past 40 years by a factor of 1.4- to 4-fold.^{2,4,7} Crohn's disease is more common in white than in African Americans or Asian, and the gender distribution is equal.^{2,4,7} There is a sevenfold to eightfold increase of Crohn's disease among Jews. The rates are highest for American Jews and much lower in Israeli-born and non-Ashkenazi Jews. These disparate rates found in different countries suggest the likelihood of hereditary predisposition, which may be altered by environmental factors.^{2,4,7} Crohn's disease has a bimodal age distribution. The peak incidence is between the ages of 15 and 25 years, with a lower peak between 50 and 80 years. It occasionally occurs in children as young as 2 years old.^{2,4,7}

Crohn's disease is generally acknowledged to be more common in urban than in rural populations, but the literature is conflicting on this matter.^{2,4,7} Epidemiologic data have shown that 4.5% to 16.6% of patients with Crohn's disease have a positive family history. The disease is 30 times more frequent in siblings than in the general population. Familial IBD seems to follow a polygenic inheritance pattern.^{2,4,7}

Crohn's disease runs a clinical course, with seasonal exacerbations. The highest relapse rate is found in the autumn and winter; the lowest is seen in the summer. This pattern suggests that seasonal or exogenous factors may be involved in relapse.^{2,4,7} Although nonsmoking is a feature of ulcerative colitis, patients with Crohn's disease are four times more likely to be smokers than matched controls.^{2,4,7}

The mortality rate of Crohn's disease has significantly declined, which can be attributed to improvements in diagnosis and management. The mortality rates for all IBDs for white American men were 5.88/1 million in 1970 to 1971 and 2.68/1 million in 1982; the rates for white American women were 7.24 and 3.48/1 million population, respectively.¹²

FINDINGS

Clinical Findings

The clinical manifestations of Crohn's disease are protean.^{2,4,11} The most frequently encountered initial features are rectal

bleeding, diarrhea, and abdominal pain. Two major types of pain occur in patients with Crohn's disease. The first is often mild, colicky, situated in the lower abdomen, and relieved by defecation. It tends to occur in association with diffuse Crohn's disease involving the colon and simulates the pain of ulcerative colitis. The second type is more severe; it is often situated in the right lower quadrant, simulating appendicitis. In a World Gastroenterology Organisation (WGO) survey, 75% of patients with Crohn's disease had abdominal pain at presentation.^{2,4,11}

Some degree of diarrhea usually accompanies active Crohn's disease, but it is less severe than the often explosive diarrhea of ulcerative colitis. Almost 50% of all patients with Crohn's colitis experience at least minor rectal bleeding during the active phase of disease. Profuse bleeding is much more common in ulcerative colitis. The presence of mucus in the stool is also more frequent in ulcerative colitis than in Crohn's disease. Many of the most severe symptoms reflect complications such as abscess, fistula, and perianal lesions rather than Crohn's disease itself.

The physical examination of patients with IBD is often normal in quiescent disease. In severe cases, pallor, dehydration, anemia, weight loss, finger clubbing, abdominal distention, tachycardia, and fever may be found. Abdominal tenderness and distention, pronounced wasting, and emaciation are more frequently found in Crohn's disease than in ulcerative colitis. An intra-abdominal mass is common in Crohn's disease but is rarely present in ulcerative colitis. The masses and tenderness usually occur on the right side in patients with Crohn's disease.

No examination of the patient with possible IBD is complete without a detailed rectal examination, including sigmoidoscopy. Circumferential, confluent, and contiguous inflammatory changes were found in 96% of patients with ulcerative colitis in the WGO series.^{2,4,11} Patchy, inflammatory changes with areas of normal intervening mucosa were highly suggestive of Crohn's disease, occurring in two thirds of patients with Crohn's proctosigmoiditis. Simple inspection may reveal severe perianal disease, which strongly suggests the diagnosis of Crohn's disease.^{2,4,11}

Endoscopic Findings

Aphthoid lesions, cobblestoning, and ulcers in an area of otherwise apparently normal mucosa are diagnostic of Crohn's disease versus ulcerative colitis but can be seen in other colitides. Mucosal granularity and friability are common in early ulcerative colitis but may be a late finding in Crohn's colitis. The rectum is often grossly normal in patients with Crohn's disease, and involvement is typically asymmetric and discontinuous.^{2,4,14}

Radiologic Findings

Radiography. When confined to the colon, Crohn's disease (Fig. 57-18) has features similar to those of ulcerative colitis on radiographs. An extended gas-filled stricture of the colon is suggestive of granulomatous colitis but can also be seen in ulcerative colitis, carcinoma, and healing ischemic colitis.^{16,21}

Small bowel obstruction can be seen on radiographs in patients with Crohn's disease of the small bowel. It is uncommon to identify stenotic small bowel segments on radiographs because gas is not found in the small bowel as often as is found in the colon. Occasionally, a markedly dilated segment of small bowel, reminiscent of a dilated loop of small bowel volvulus or Meckel's diverticulum, can be seen between two stenotic areas.^{16,21} Evidence of nephrolithiasis, gallstones, ankylosing

Figure 57-18 Crohn's disease: plain radiograph. The ascending colon is tubular and ahaustral. Note the mural thickening (arrows).

spondylitis, sacroiliitis, avascular necrosis of the femoral heads, and disorders associated with Crohn's disease and its therapy should also be sought on abdominal radiographs.

Barium Enema

The barium enema features of Crohn's colitis are listed in Table 57-1 and summarized in Figure 57-19, and will be discussed here in more detail.

Lymphoid Hyperplasia. Lymphoid follicles are a normal component of gut-associated lymphatic tissue. They are aggregates of lymphocytes surrounding germinal centers that straddle the muscularis mucosae. Lymphoid follicles have an average macroscopic density of 3.8/cm of adult human colon.^{25,103} They are

Figure 57-19 Spectrum of radiologic changes in Crohn's colitis on double-contrast barium enema examinations. A. 1, Perianal disease: ulcers, abscess, fissures, anocutaneous fistula; 2, deep rectal ulcers; 3, normal rectum in 50% of cases; 4, island ulcer; 5, circular discrete ulcers; 6, aphthoid ulcers; 7, serpiginous ulceration formed by coalition in a longitudinal form of circular and island ulcers; 8, thickening of the bowel wall; 9, normal skip areas; 10, rose thorn-shaped fissures; 11, transverse stripes of Welin (en face fissures or crevices between adjacent swollen mucosal folds); 12, linear confluent intramural ulceration, "double tracking"; 13, stricture (25% of cases); 14, eccentric disease, not involving the entire circumference; 15, pseudosacculations, produced by fibrosis of the opposite wall; 16, deep pleomorphic ulcers—composite, horned, sacular; 17, a normal patch surrounded by disease (and patches of disease surrounded by normal mucosa also occur); 18, inflammatory and postinflammatory pseudopolyps; 19, cobblestone mucosa— islands of residual swollen mucosa bounded by intersecting linear ulcers; 20, right-sided disease with normal rectum and distal colon; 21, contracted, cone-shaped cecum; 22, enlarged ileocecal valve usually associated with involvement of the terminal ileum; 23, small bowel disease in 60% of cases; 24, ileocolic fistula. **B.** Further depiction of mucosal abnormalities in Crohn's colitis. (**A** from Simpkins KC: *Inflammatory bowel disease: Ulcerative and Crohn's colitis*. In Simpkins KC [ed]: *A Textbook of Radiological Diagnosis*, vol 4, *The Alimentary Tract: The Hollow Organs and Salivary Glands*. London, HK Lewis, 1988, pp 473–498; **B** from Bartram CI, Kumar P: *Clinical Radiology in Gastroenterology*. Oxford, England, Blackwell Scientific, 1981, p 138.)

seen in 50% of barium studies performed on children and 13% of air-contrast barium enemas in adults. Lymphoid follicles appear as 1- to 3-mm elevations in the mucosa, without a ring shadow.^{103,104}

Lymphoid follicles may enlarge in a wide variety of infectious, neoplastic, immunologic, and inflammatory diseases of

the gut, including Crohn's disease.¹⁰⁵ Prominent lymphoid follicles have also been observed in older patients with colonic adenomas and carcinomas.¹⁰⁶

Aphthoid Ulcerations. As the lymphoid follicles enlarge, the overlying mucosa may ulcerate with production of the

aphthous lesion. These small superficial ulcers have erythematous margins and are seen on a background of normal or near-normal mucosa.²⁵ This is in direct contrast to ulcerative colitis, in which ulceration invariably occurs against a background of heavy inflammation. Aphthae are recognized radiographically as punctate central collections of barium surrounded by a radiolucent halo about 1 mm in diameter that produces a target or bull's-eye appearance (Fig. 57-20).¹⁰⁷⁻¹¹³ Aphthae may be isolated, found in clusters, or involve the entire colon.¹⁰⁸

Aphthoid lesions are found in 44% to 72% of patients with Crohn's disease and may be the only abnormality found in an otherwise normal colon.^{2,4,109} These ulcers are nonspecific and occur in amebiasis, salmonellosis, shigellosis, herpes, cytomegalovirus infection, Behçet's disease, ischemic colitis, and *Yersinia* enterocolitis.^{2,4}

Cobblestoning. The aphthous lesions may regress, remain stable or, more commonly, enlarge and deepen.^{111,113} As the aphthae expand, they become irregular in outline and lose their surrounding lucent halo. Adjacent ulcers may coalesce, forming a network of longitudinal linear ulceration and transverse fissuring, with edematous intervening mucosa producing a raised, cobbled appearance (Fig. 57-21).¹⁵ As noted, this condition is actually one of many forms of inflammatory pseudopolyposis.

Deep Ulcerations. Fissuring ulcers (Fig. 57-22) are a distinctive feature of Crohn's disease. They typically penetrate beyond the submucosa, with resultant knife-shaped or rose thorn fistulas.²⁵ These fissures and fistulas do not cause pneumoperitoneum because the surrounding serosa is inflamed, and involved bowel

Figure 57-20 Crohn's disease: aphthoid ulcerations. **A.** Photomicrograph demonstrates an enlarged lymphoid follicle with overlying ulceration (arrow). **B to D.** Double-contrast barium enema in different patients demonstrates aphthoid lesions (arrows) of varying sizes in the cecum (**B**), transverse colon (**C**), and sigmoid colon (**D**).

Figure 57-21 Crohn's disease: cobblestone mucosa. Longitudinal and transverse ulcers of the transverse colon produce a cobblestone appearance.

loops become adherent to one another and adjacent peritoneal surfaces.^{25,39,40}

Sinus Tracts, Fissures, and Fistulas. Sinuses, fissures, and fistulas (Fig. 57-23) are a hallmark of Crohn's disease.^{2,4,11} Sinuses and fissures represent blind-ended inflammatory tracts that penetrate through the full thickness of the muscle coat later in the disease course. Fistulas communicate with other structures. Anatomic evidence suggests that mechanical factors, such as elevated intraluminal pressure, rather than any intrinsic pathologic change of Crohn's disease, are responsible for these fissures and fistulas.² This suggestion is based on the fact that there is a significant coincidence of sinuses and strictures and that sinuses arise proximal to the point of maximal stricture. In addition, fissures, sinuses, and fistulas are not constantly associated with myocytolysis, a seemingly necessary process if only the Crohn's inflammation is required for the fissuring.^{2,4}

Long interconnecting fistulas are common in Crohn's colitis and occur in the muscularis mucosae or subserosa paralleling the bowel lumen. When not associated with neoplasia or diverticula, pericolic sinus tracts are suggestive of Crohn's disease.²⁵⁻²⁷

Mural Thickening. The mural thickening that occurs in Crohn's disease is more impressive than that found in ulcerative colitis. It is caused by transmural inflammation and fibrosis. The submucosa may also accumulate fat in Crohn's disease but less commonly than in ulcerative colitis. CT well demonstrates mural thickening of the esophagus, stomach, duodenum, small bowel, and colon when these areas are involved by Crohn's disease.

Luminal Narrowing and Strictures. Crohn's disease is a transmural inflammatory process that produces gut wall thickening and fibrosis, leading to narrowing of the lumen and shortening of the gut as well.^{2,4,6} In ulcerative colitis, narrowing results from thickening and contractions of the muscularis mucosae rather than from fibrosis. Strictures are asymmetric in Crohn's disease and tend to be less smooth and circumferential than those seen in ulcerative colitis. Strictures occur in 21% of patients with small bowel disease and in 8% of patients with Crohn's colitis.²⁸

Sacculations. The transmural fibrosis of Crohn's disease is often asymmetric. It occurs predominantly on the mesenteric side of the gut, where it is often accompanied by creeping fat of the mesentery. The relatively unaffected side (usually antimesenteric) remains pliable and tends to bulge when luminal pressure increases because of peristalsis. Outpouchings may eventually develop. The outpouchings are similar to the so-called pseudosacculations (Fig. 57-24) or pseudodiverticula seen in scleroderma.^{25,27}

Anorectal Disease. Anorectal complications are common in patients with Crohn's disease (Fig. 57-25) and include anal fissures, ulcers, abscess, internal hemorrhoids, and stenosis with induration, skin lesions such as erosion, skin tags, ulceration, maceration, external hemorrhoids, and abscess, and fistulas—anal canal to skin, rectum to skin, and rectovaginal. Anal disease develops in 36% of all patients with Crohn's disease, 25% of those with only small bowel involvement, 67% of those with colonic disease, and nearly all patients with rectal disease.³¹ In approximately 25% of patients, the anal disease may antedate overt intestinal disease, often by 4 years. Accordingly, development of these anorectal disorders warrants radiologic investigation of the entire gastrointestinal tract.^{2,4,31}

Distribution. Any portion of the gut, from the mouth to the anus, may be involved by Crohn's disease. Twenty percent of cases are isolated to the colon, 20% are restricted to the small bowel, and 60% involve the colon and small bowel simultaneously. In 5% to 10% of these patients, upper gastrointestinal tract involvement is seen. It is unusual to see isolated esophageal or gastroduodenal Crohn's disease. Regardless of location, radiographic and pathologic findings are similar; there is discontinuous, patchy, and asymmetric disease involvement.^{2,4,6}

Computed Tomography

Crohn's disease is manifested on CT (see Box 57-3) by bowel wall thickening of 1 to 2 cm.¹¹⁴ This thickening, which occurs

Figure 57-23 Crohn's disease: fistulas and sinus tracts. **A.** Fistula (arrow) between the sigmoid colon and adjacent small bowel is demonstrated on barium enema study. **B.** Barium enema examination shows fistula between transverse colon and duodenum. **C.** Paracolic sinus tract (arrow) is demonstrated in a patient with previous resection of transverse colon and an ascending-descending colon anastomosis.

in 83% of patients, is usually observed in the terminal ileum, but other portions of the small bowel, colon, duodenum, stomach, and esophagus may be similarly affected.^{62,65}

During the acute, noncicatrizing phase of Crohn's disease, the small bowel and colon maintain mural stratification (Fig. 57-26) and often have a target or double halo appearance.^{56,115} As in ulcerative colitis, there is a soft tissue density ring (corresponding to mucosa), which is surrounded by a low-density ring with an attenuation near water or fat (corresponding to submucosal edema or fat infiltration), which in turn is surrounded by a higher density ring (muscularis propria).¹¹⁶ Inflamed mucosa and serosa may show significant contrast enhancement after IV bolus contrast administration; the intensity of enhancement correlates with the clinical activity of disease.¹¹⁷

The CT demonstration of mural stratification (i.e., the ability to visualize distinct mucosal, submucosal, and muscularis propria layers) indicates that transmural fibrosis has not occurred and that medical therapy may be successful in ameliorating lumen compromise.⁵⁶ The edema and inflammation of the bowel wall that cause mural thickening and lumen obstruction are reversible to some extent. A modest decrease in wall thickness often produces dramatic increase in the luminal cross-sectional area and resolution of the patient's obstructive symptoms. In patients with long-standing Crohn's disease and transmural fibrosis, mural stratification is lost, so the affected bowel wall typically has homogeneous attenuation on CT.⁶⁷ Homogeneous attenuation of the thickened bowel wall in the

presence of good intravascular contrast medium levels and thin section scanning suggests irreversible fibrosis, so anti-inflammatory and immunosuppressive agents may not provide significant reduction in bowel wall thickness.⁹⁹ If these segments become sufficiently narrow, surgical resection or strictureplasty may be necessary to relieve the patient's obstruction. Not uncommonly, acute and chronic changes of Crohn's disease can coexist (Fig. 57-27).

Mesenteric Involvement. The palpation of an abdominal mass or separation of bowel loops on a small bowel series in a patient with Crohn's disease evokes a large differential diagnosis—abscess, phlegmon, “creeping fat” or fibrofatty proliferation of the mesentery, bowel wall thickening, and enlarged mesenteric lymph nodes. Each of these disorders has significantly different prognostic and therapeutic implications.^{99,118,119} This diagnostic dilemma is further complicated by the fact that many patients are receiving immunosuppressive therapy that can mask signs and symptoms. CT can readily differentiate the extraluminal manifestations of Crohn's disease.

Fibrofatty Proliferation of the Mesentery. Fibrofatty proliferation, also known as creeping fat of the mesentery, is the most common cause of separation of bowel loops seen on small bowel series in patients with Crohn's disease.^{120,121} On CT, the sharp interface between bowel and mesentery is lost, and the attenuation value of the fat is elevated by 20 to 60 HU as a result of the influx of inflammatory cells and fluid.⁶¹ Mesenteric

Figure 57-24 Crohn's disease: sacculations. Crohn's disease involves primarily the mesenteric side (arrows) of the gut, leading to fibrosis and ballooning of the antimesenteric border. Crohn's disease is typically discontinuous, patchy, and asymmetric.

adenopathy with lymph nodes ranging in size from 3 to 8 mm may also be present. If these lymph nodes are larger than 1 cm, lymphoma or carcinoma, both of which occur with greater frequency in Crohn's disease, must be excluded.

There is subserosal accumulation of an increased amount of hypertrophied fat as a result of perivascular inflammation with fibrosis and contraction of the muscular properties. The perivascular fibrosis results in the contraction of dilated feeding vessels and hypertrophied mesenteric fat, tethering the mesentery closer to the gut wall. This tethering contributes to the gross appearance of fat wrapping around the gut.¹²²

Contrast-enhanced CT scans often show hypervascularity of the involved mesentery manifesting as vascular dilation, tortuosity, prominence, and wide spacing of the vasa recta. These distinctive vascular changes have been termed *vascular jejunization of the ileum* or the *comb sign*.¹²¹ Identification of this hypervascularity should suggest active disease and may be useful in differentiating Crohn's disease from lymphoma and metastases, which tend to be hypovascular lesions.

Phlegmon. A phlegmon is an ill-defined, inflammatory mass in the mesentery or omentum that may resolve completely with antibiotics or progress to form an abscess.¹⁰⁹ Phlegmons are another common cause of mesenteric mass effect in patients with Crohn's disease. On CT, a phlegmon produces loss of

definition of surrounding organs and a smudgy or streaky appearance of the adjacent mesenteric or omental fat.⁶⁶

Abscess. Of patients with Crohn's disease, 15% to 20% eventually develop an intra-abdominal abscess.¹²² Abscesses are most frequently associated with small bowel disease or ileocolitis.¹²³ Once developed, an abscess can burrow through the adjacent tissue or break open and drain spontaneously into another part of the bowel, adjacent organs, or both. Abscesses usually result from sinus tracts, fistulas, perforations, or surgery for Crohn's disease.

An intra-abdominal abscess may be difficult to diagnose on clinical grounds in patients with Crohn's disease because symptoms may be inconspicuous, masked by corticosteroids, or mistaken for an exacerbation of disease. Barium studies and endoscopy can only suggest the presence of an abscess indirectly by mass effect, spiculation of the mucosa, or identification of a fistula. Also, these studies do not evaluate the ischiorectal fossa, psoas muscle, and solid abdominal organs, which are common locations of abscess formation.^{123,124} Cross-sectional imaging is required to confirm the diagnosis and reveal the full extent and location of the abscess cavity. CT is the primary imaging tool used for percutaneous drainage of Crohn's disease-related abscesses.¹²⁵⁻¹²⁷

Transrectal Ultrasonography

Transrectal ultrasonography can show the following abnormalities in patients with Crohn's disease: (1) mural thickening; (2) perianal and perirectal abscesses and fistulas; and (3) heterogeneity of the anal sphincter.⁷³ Rectal wall thickening (>4 mm) is often accompanied by loss of mural stratification in Crohn's disease.⁷³

The anal sphincter derives from the rectal muscular layer as a sharply delineated ellipsoid that is uniformly hypoechoic. When involved by Crohn's disease, the sphincter becomes heterogeneous, with echogenic zones interspersed between the normal hypoechoic regions. Also in patients with active proctologic disease, the shortening and narrowing of the anal canal during squeezing and elongation with dilation during straining are less pronounced. Fistulas and sinus tracts appear as a dotted column of echo-rich gas bubbles, with reverberation on transrectal ultrasonography. Abscesses are characterized sonographically as predominantly hypoechoic areas that contain echogenic elements corresponding to debris and gas bubbles. The wall of the abscess is usually thick and irregular, and some posterior acoustic enhancement may be seen. Some authors advocate routine screening with transrectal ultrasonography because this technique is capable of defining pararectal and para-anal abscesses and fistulas that develop extramurally without mucosal lesions.^{2,4,11}

Transabdominal Ultrasonography

The thickness of the colonic and small bowel wall can be appreciated sonographically, and the validity of using mural thickening in establishing the diagnosis of IBD has a reported sensitivity of 67% to 86% and specificity of 87% to 100%.⁶⁸⁻⁷² Some authors suggest using ultrasonography as a screen for IBD.⁶⁸⁻⁷² When suspicion of disease is low, normal ultrasonography may be sufficient to avoid barium examination. When abnormal gut is seen or clinical suspicion is high, despite a normal ultrasound study, barium examination should be performed.⁶⁸⁻⁷²

Figure 57-25 Crohn's disease: anorectal pathology. **A.** Multiple cutaneous fistulas are seen in the perianal region. **B.** Barium enema study shows a sinus tract (arrow) into the right perianal soft tissues. **C.** Coronal, fat-suppressed T2-weighted MRI scan of the anorectum shows multiple high signal intensity fistulas (arrows) into the perianal and mesorectal fat. **D.** Axial MRI scan shows mural thickening of the rectum, with a fistula (arrow) extending into the left piriformis muscle. **E.** CT scan shows a U-shaped abscess along the posterior aspect of the anorectal junction (arrow).

In patients with active Crohn's disease, the colon wall can be 1.5 cm thick. Mural stratification is typically lost as well. Using criteria listed in [Box 57-4](#), the sensitivity of ultrasound in detecting active Crohn's disease was 91%, with a specificity of 100%; sensitivity was 89%, with a specificity of 97% for detecting active ulcerative colitis. Several sonographic caveats should be noted. In patients with only aphthoid ulcerations, typical wall stratification is maintained in patients with Crohn's disease, suggesting that the disease is not yet transmural. In patients with ulcerative colitis who have large and extensive pseudopolyps, the thickness of the colon wall may approach 1.5 cm, and mural stratification may be lost.⁶⁸⁻⁷²

Several authors have questioned the usefulness of ultrasound for differentiating ulcerative colitis and Crohn's colitis on the basis of bowel wall changes alone.⁶⁸⁻⁷² Documentation of continuous or discontinuous involvement, combined with evidence of mesenteric disease, abscess, or fistula, can assist differentiation.

In a study using hydrocolonic ultrasonography, 93% of patients with Crohn's disease showed loss of mural stratification, and the wall appeared hypoechoic and clearly thickened. In contrast, mural stratification was maintained in ulcerative colitis.⁶⁸⁻⁷² Hydrocolonic ultrasonography could differentiate Crohn's disease from ulcerative colitis in 93% of cases. Colonic Crohn's disease was detectable by this technique with a sensitivity of 96% and specificity of 91%.⁶⁸⁻⁷²

The thickened bowel wall in Crohn's disease ([Fig. 57-28](#)) produces a target, bull's-eye, or cockade appearance that must be differentiated from chronic ulcerative colitis, diverticulitis, lymphoma, ischemic colitis, and pseudomembranous colitis.⁶⁸⁻⁷² Ultrasonography has also successfully diagnosed recurrent disease in patients who have had surgical resections.⁶⁸⁻⁷² Sonographically, creeping fat of the mesentery is hypoechoic compared with normal fat resulting from edema.⁶⁸⁻⁷²

Doppler sonographic evaluation of the superior mesenteric artery is a promising noninvasive method of detecting ileocolic inflammation in patients with Crohn's disease and assessing disease activity. In patients with active disease, there is an increase in blood flow and decrease of resistive index of the superior mesenteric artery. Scans are performed preprandially, and postprandial scans can provide additional information. In normal subjects, there is a significant difference in the resistive index before and after meals because of the vasodilation and increased diastolic flow that occur after a meal. In patients with Crohn's disease, there is massive and persistent vasodilation, related to the extent and severity of disease, which increases blood flow and decreases the resistive index. Accordingly, a meal in patients with active disease does not produce expected Doppler changes because the vasodilation is already established.¹²⁸⁻¹³⁰

In patients with active ileocecal Crohn's disease, alterations of intestinal vascular impedance may reflect the Doppler waveform of the superior mesenteric artery. This change in vascular

Figure 57-26 Crohn's disease: acute disease on CT. Coronal reformatted image shows mural thickening of the ascending (yellow arrows) and descending (red arrows) colon, with engorgement of the vasa rectae indicating active, acute disease.

impedance is manifest by increased flow velocities (peak systolic and diastolic) in the superior mesenteric artery flow volume to the superior mesenteric artery territory. Increased flow velocities are caused by the hyperemia and increased flow, as well as decreased downstream resistance.¹²⁸⁻¹³⁰

Magnetic Resonance Imaging

MRI provides a similar perspective to CT in that images demonstrate the overall topography of the abdomen. This imaging technique has several inherent advantages—lack of ionizing radiation, multiplanar imaging capability, and superb soft tissue contrast.⁷⁵⁻⁷⁹ Disadvantages that have generally precluded the routine use of MRI in the evaluation of IBD include respiratory and bowel motion artifact, lack of a satisfactory oral contrast agent, high signal intensity of intra-abdominal fat, and long imaging times used in conventional spin-echo sequences.

Many of the limitations of MRI have been overcome by using breath-holding imaging (fast low-angle shot [FLASH]), fat suppression, and an IV contrast agent, gadopentetate dimeglumine (Gd-DTPA).^{131,132} With these new techniques, MRI can show the extent and severity of inflammatory changes of the gut (see Fig. 57-25) that correlate with endoscopic and histologic findings from surgical specimens.⁷⁵⁻⁷⁹ Mural thickening of the gut can also be appreciated with MRI. When fast imaging sequences are combined with IV contrast material (Gd-DTPA) administration and fat-suppressed imaging, a good correlation among

Figure 57-27 Coexisting acute and chronic Crohn's disease: CT findings. There is stenosis of the distal transverse colon (yellow arrow), indicating chronic disease. There is also some hyperenhancement of the mucosa of the more proximal transverse colon with engorgement of the vasa rectae (white arrow), indicating coexisting active disease.

Figure 57-28 Crohn's disease: sonographic findings. Longitudinal sonogram of the ascending colon shows hypervascularity and mural thickening.

bowel wall thickness, length of diseased bowel, and severity of inflammation has been reported.⁷⁵⁻⁷⁹ The percentage contrast enhancement compares well with severity of inflammation based on endoscopic and surgical findings. The actively inflamed wall enhances because of increased delivery of the agent and increased capillary permeability. On T1-weighted MR sequences, the fat may have low signal intensity streaks and strands. These

areas may enhance after Gd-DTPA administration on gradient-echo images. MRI is sensitive for the detection of perianal and perirectal fistulas, sinus tracts, and abscesses that frequently accompany perianal Crohn's disease.^{133,134}

THERAPY

Medical Management

Crohn's disease does not behave clinically as a single disorder, so each patient must receive an individual clinical evaluation and integrated medical and surgical management.^{2,4,11}

Drug Therapy. Corticosteroids are the most effective therapy for producing symptomatic relief in Crohn's disease patients. Although they are effective in preventing relapses, they do not alter the long-term outcome and are associated with complications related to Cushing's disease. Immunosuppressive agents have also been tested, with encouraging results. Several studies have shown that cyclosporine is effective when conventional corticosteroids have failed and that it works more quickly than other immunosuppressive agents. Its efficacy is related to its ability to interfere with T-cell activation. Side effects include malabsorption and renal toxicity, and there is the long-term risk of cyclosporine-induced neoplasm.^{2,4,11}

The role of azathioprine in Crohn's disease remains controversial because it produces a variety of significant side effects. Physicians are often compelled to use azathioprine as a third-line drug, particularly in patients with extensive small bowel disease, recurrence after surgery, and fistulas. In some patients, the use of azathioprine or its active metabolite, 6-mercaptopurine, has permitted reduction in the dose of corticosteroid and even discontinuation of the drug.

Mesalamine decreases recurrence rates in Crohn's colitis, but its value for small bowel disease is uncertain. The use of sulfasalazine is hindered by side effects, which has led to the development of less toxic derivatives of 5-aminosalicylic acid.

The efficacy of metronidazole in Crohn's disease remains unproved, and its use is limited by neurologic toxicity. However, this therapy may lead to complete remission of perianal disease and the closure of fistulas.^{2,4,11}

Total parenteral nutrition (TPN) is useful for maintaining nutritional status when the gut cannot be used during exacerbations of inflammatory or fibrostenotic Crohn's disease. Nevertheless, remission rates while maintained on TPN and bowel are equivalent to those of enteral nutrition. TPN for 5 to 10 days preoperatively can decrease surgical complications in patients who require bowel resection.

Advances in understanding of the role of immune cells, natural killer cells, and macrophages and their soluble mediators, such as cytokines and tumor necrosis factor, have led to the development of specific immunotherapies with improved efficacy and reduced toxicity. As noted, anti-TNFs (chimeric, monoclonal antibody [infliximab]) have proved helpful in patients with advanced Crohn's disease refractory to corticosteroids and immunosuppressive therapy. This recombinant antibody is given as a single IV dose and can rapidly close fistulas, with improvement lasting for 3 months.^{2,4,11}

Surgical Management

There is a high rate of recurrence (30% to 53%) of Crohn's disease after resection of diseased bowel.^{2,4,88,91} It is possible

that Crohn's disease affects, at least at a microscopic level, the entire gut from the outset, so the disease cannot be cured by surgery. Therefore, surgery should be reserved for certain complications of the disease or for unequivocal failure to respond to optimal medical therapy. These guidelines are particularly applicable to two groups of patients, those who have previously undergone small bowel resection and present with recurrent disease of an obstructive nature and those who have diffuse disease and multiple small bowel strictures. Removal of all the diseased areas in these patients may lead to short bowel syndrome.

The major indications for surgery in Crohn's disease are obstruction, perforation, hemorrhage, and carcinoma.^{2,4,88,91} Abscesses and fistulas should first be treated by the interventional radiologist because this may save the patient from having surgery.^{2,4,88,91}

There is considerable interest concerning strictureplasty, and early reports have suggested that this technique is effective in treating short, stenosing Crohn's lesions of the small bowel.^{2,4,88,91} One series reported 24 patients who had 86 strictureplasties.⁸⁸ This procedure was safe and effective for select patients undergoing surgery for obstructive Crohn's disease. Short fibrous strictures in patients who did not have acute inflammatory segments of disease were most amenable to strictureplasty. Another report compared recurrence after strictureplasty with that after primary resection for small intestinal Crohn's disease.⁸⁸ No difference in the rate of recurrence after strictureplasty or resection was found, offering more support to the choice of strictureplasty for select patients with obstructive symptoms.

Reports of radiologically guided balloon dilation of strictures are also of interest, but this method is unlikely to be suitable for many Crohn's strictures, which are located in the small bowel.^{2,4,88,91} Current surgical opinion holds that external fistulas unassociated with residual Crohn's disease should be managed along conventional lines but that fistulas arising from diseased small intestine may require surgery. This surgery should be performed after an associated abscess has been drained, metabolic deficits have been corrected, and the anatomy of the fistula has been defined.⁹¹

Primary fistulotomy has been shown to be a safe procedure in selected patients, provided that aggressive medical treatment is used to control bowel disease preoperatively.^{2,4,88,91} Rectovaginal fistulas are especially difficult to treat, but with prolonged conservative treatment, the rectum can be preserved in many cases.

PROGNOSIS

The manifestations and complications of Crohn's disease are so diverse and unpredictable that for some patients the outlook is bleak. Disease remission can be interrupted by exacerbations at any time. Approximately 50% of patients develop complications that require surgery, and 10% to 20% lead symptom-free lives after one or two attacks. In view of the serious nature of Crohn's disease and its complications, the mortality is low. With proper medical supervision, most patients adjust remarkably well to their chronic illness and lead productive lives.^{2,4,11,133-137} The use of biologic agents such as Remicade and Humira have the potential to improve the natural history of this disease significantly.

Intestinal Complications of Inflammatory Bowel Disease

Table 57-2 summarizes gastrointestinal complications in ulcerative colitis and Crohn’s disease.

CARCINOMA

The risk of developing colorectal cancer is significantly higher in patients with ulcerative colitis and Crohn’s colitis than in the general population, although the precise magnitude of this risk

is uncertain.^{1-6,138} Studies have suggested an annual incidence of 10% after the first decade of ulcerative colitis. The risk of colorectal cancer also increases with increasing extent of disease; 75% to 80% of patients who develop cancer have pancolitis.¹³⁸ Carcinomas associated with ulcerative colitis are multiple in almost 25% of cases; they are more often flat and scirrhous than in patients without colitis and thus harder to detect.

Cancer screening has become a popular and controversial issue in patients with IBD. Since the 1960s, mucosal dysplasia has been considered a precursor of colon cancer or at least a marker of colons at risk for developing cancer. Mucosal dysplasia is often detected near or remote from the neoplasm in ulcerative colitis patients with carcinoma. However, dysplasia is patchy, inconsistent, and unpredictably distributed in the colon. Accordingly, colonoscopy with multiple, random biopsy specimens and biopsy specimens from masses or raised areas is recommended. Flow cytometry searching for aneuploidy has been advocated as a means of increasing the specificity and prognostic significance of the histologic results.

Molecular markers, such as Ki-67, DPC-4, and DYS nuclear matrix proteins, are a means of further refining the diagnosis of dysplasia and may eventually provide an alternate method of predicting colorectal cancer. Clinical studies provide support for the increasingly prevalent recommendation that any dysplasia warrants colectomy.^{2,4,11}

Several studies have shown that certain dysplastic lesions are radiologically visible (Fig. 57-29). When the dysplasia is elevated and plaquelike or multinodular, it manifests en face as irregular nodular areas with sharply angulated borders, having a mosaic tile appearance. Tangentially, these lesions project only 1 to 2 mm above the adjacent normal mucosa. When the dysplasia assumes a more polypoid form, it is indistinguishable from an adenomatous polyp. Most dysplasias occur in flat mucosa and therefore are not detectable on double-contrast barium studies. The management of high-risk patients with

TABLE 57-2 Relative Frequency of Gastrointestinal Complications in Inflammatory Bowel Disease		
Complication	Ulcerative Colitis (%)	Crohn’s Disease (%)
Anorectal lesions	<20	20-80
Fissure in ano	<15	25-30
Perianal abscess	<10	20-25
First symptom	Very infrequent	20-25
Fistula in ano	<6	20-25
Multiple and complex	Never	Common
Multiple anorectal complications	Very infrequent	20
Massive hemorrhage	3	<3
Colon	Never	<2
Small bowel		
Intra-abdominal abscess	Very rare	20-40
Internal fistulas	Very rare	Very uncommon
Free perforation	Uncommon	<8
Toxic megacolon	2-10	Less common
Pseudopolyposis	15-30	Very common
Strictures	11-15	15-25

Colitic carcinomas often have an atypical appearance. **A.** Unusual polypoid carcinoma in the proximal descending colon. **B.** There is an infiltrative plaquelike carcinoma of the hepatic flexure (solid arrows). A small macrodysplastic lesion (curved open arrow) is present proximal to the carcinoma.

ulcerative pancolitis requires regular radiologic and endoscopic surveillance for detecting dysplasia.¹³⁸⁻¹⁴⁴

TOXIC MEGACOLON

Toxic megacolon is the most severe, life-threatening complication of IBD. It occurs in 1.6% to 13% of patients with ulcerative colitis and is less common in Crohn's colitis. Toxic megacolon usually occurs in patients in their 30s and may be the initial manifestation of ulcerative colitis. It is the most common cause of death directly related to ulcerative colitis and is an indication for emergency surgery.¹⁴⁵⁻¹⁴⁸

Pathologic Findings

On pathologic examination, there is transmural inflammation with deep fissuring ulcers into the muscularis propria, often with extension to the serosa. These inflammatory changes may be so extensive that large areas of denuded mucosa are seen. The colon undergoes disintegration of normal tissue cohesion, an appearance that surgeons have likened to having the consistency of wet tissue paper on handling. The inflammatory exudate seeps through the serosa and may lead to signs of peritonitis, even without frank perforation. The external surface of the colon shows intense serositis, and the greater omentum and gastrocolic ligament are edematous and inflamed. These changes are accompanied by vasculitis of the small arterioles and inflammation and by destruction of the ganglion cells of the myenteric and submucosal plexuses; there is myocytolysis in the muscularis propria.^{2,4,6} Although the bowel wall appears thickened and nodular on abdominal radiographs, the specimen often shows a mural thickness of only 2 to 3 mm in areas of denuded mucosa.

A number of factors that further contribute to high intraluminal pressures and decreased muscle tone that can lead to colonic distention in toxic megacolon include antidiarrheal drugs (e.g., codeine, morphine, tincture of opium), aerophagia, and hypokalemia. Barium enema has also been implicated as a precipitating factor in toxic megacolon, but this is controversial. Certain evidence suggests that the relationship may be temporal more than a cause and effect phenomenon. Nevertheless, the interdiction concerning barium enema studies in patients who are severely ill with ulcerative colitis is valid.^{2,4,6} Toxic megacolon can also complicate other forms of colitis, such as ischemic colitis, Crohn's disease, pseudomembranous colitis, and amebiasis.

Radiologic Findings

Toxic megacolon (Fig. 57-30) is one of the few life-threatening conditions in which an abdominal radiograph is all that is required to establish a firm diagnosis.¹⁴⁸ Dilation is the hallmark of toxic megacolon; mean diameters of the most dilated segments are between 8.2 and 9.2 cm. Dilation more than 5 cm indicates ulceration to the muscle layer and should be considered the threshold for dilation in fulminating colitis. In the past, the transverse colon was considered the focus of disease, but this only reflects the fact that the transverse colon is the least dependent portion of the large intestine on supine view radiographs. Initially, only a short segment of colon may be involved.^{2,4}

Mucosal islands are a common finding in toxic megacolon and indicate severe disruption of the mucosa. This appearance can be simulated in patients with inflammatory polyps during an acute attack. As noted, although the colon wall is thin

Figure 57-30 Intestinal complications of ulcerative colitis: toxic megacolon. Mucosal islands (arrows), deep ulcerations, and dilation establish the diagnosis.

pathologically, it appears thickened radiologically, presumably as a result of subserosal or omental edema. A radiolucent stripe may be noted running parallel to the colon, which probably represents the pericolic fat line.

The profound inflammation and extensive ulceration of toxic megacolon always abolish the haustral pattern, so that the presence of normal haustra excludes the diagnosis. Long fluid levels can be seen in the colon as well as small bowel distention, in keeping with an ileus.¹⁴⁸

Extraintestinal Complications of Inflammatory Bowel Disease

Extraintestinal manifestations develop in one fourth to one third of patients with IBD (Box 57-6).¹⁻⁷ They can be divided into three categories: (1) those intimately related to disease activity or extent of disease and are responsive to therapy directed at the bowel disease (e.g., arthritis, iritis); (2) those whose course is independent of underlying bowel disease (e.g., sclerosing cholangitis, ankylosing spondylitis); and (3) those caused by inadequate or disordered intestinal function (e.g., cholelithiasis, nephrolithiasis).¹⁻⁷

HEPATOBIILIARY COMPLICATIONS

The most frequent serious manifestations of extraintestinal IBD occur in the liver and biliary tract.¹⁻⁷ As a rule, these

BOX 57-6 EXTRACOLONIC MANIFESTATIONS OF ULCERATIVE COLITIS**HEPATOBIILIARY AND RENAL**

Nonspecific reactive hepatitis
 Sclerosing cholangitis
 Pericholangitis
 Chronic active hepatitis
 Cholangiocarcinoma
 Fatty infiltration
 Musculoskeletal
 Arthritis
 Ankylosing spondylitis
 Sacroiliitis
 Hypertrophic osteoarthropathy
 Avascular necrosis
 Ocular
 Uveitis and iritis
 Episcleritis
 Conjunctivitis
 Mucocutaneous
 Pyoderma gangrenosum
 Erythema nodosum
 Cutaneous vasculitis
 Stomatitis
 Urolithiasis and nephrolithiasis
 Amyloidosis
 Drug-related disease
 Bronchopulmonary
 Pulmonary vasculitis
 Pleuropericarditis

HEMATOLOGIC AND VASCULAR

Anemia from blood loss
 Autoimmune hemolytic anemia
 Thrombocytosis
 Thromboembolic disease
 Increased factors V and VIII
 Accelerated thromboplastin III levels
 Arteritis of aorta and subclavian artery
 Pancreas
 Drug-related pancreatitis

complications generally do not correlate with disease activity, duration, or severity, with the exception of fatty infiltration, which occurs in patients who tend to be more seriously ill, debilitated, and malnourished.¹⁻⁷

Hepatic Steatosis

Fatty liver is found on liver biopsy specimens in 20% to 25% of patients with IBD; it may be caused by fat malabsorption, hyperalimentation, sepsis, protein-losing enteropathy, malnutrition, and corticosteroids.¹⁻⁷ The imaging features of fatty liver are variable and depend on the amount of fat deposited, its distribution within the liver, and presence of associated hepatic disease. CT is the best noninvasive technique for the detection of hepatic steatosis because there is an excellent correlation between hepatic parenchymal CT attenuation and the level of hepatic fat found in liver biopsy specimens. Fatty deposition is usually diffuse; however, involvement can be focal, lobar,

segmental, or scattered in a bizarre pattern that rapidly appears and disappears.¹⁻⁷

Cholelithiasis

Of patients with Crohn's disease, 30% to 50% develop gallstones, especially those with extensive terminal ileal disease or after ileal resection. As a consequence of this ileal disease, these patients form lithogenic bile because of bile salt malabsorption or loss of the enterohepatic circulation. Ultrasonography is the primary modality for diagnosing gallstones.¹⁻⁷

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis occurs in fewer than 2% to 5% of patients with IBD; it is usually associated with ulcerative colitis.¹⁻⁷ Ultrasonography, CT, and MRI (Fig. 57-31) can directly visualize the fibrous mural thickening of the larger bile ducts that characterize this disease.^{1-7,149} The thickening may be concentric or asymmetric and usually measures 2 to 5 mm. Other suggestive diagnostic signs include focal duct dilation, discrepancy between the size of the intrahepatic and extrahepatic bile ducts, focal clustering of intrahepatic ducts, and discontinuous areas of minimal intrahepatic biliary dilation without associated hepatic, porta hepatis, or pancreatic masses. The cholangiographic signs of beading, pruning, and nodular mural thickening can also be seen on cross-sectional imaging, but usually with less detail and precision.¹⁴⁹

CT, ultrasonography, and MRI offer three major advantages in evaluating patients with known or suspected sclerosing cholangitis.¹⁴⁹ First, they are noninvasive techniques that are quite safe in these patients, who often need multiple serial examinations. Second, they can visualize the entire biliary tract in patients in whom strictures obstruct the flow of contrast medium during cholangiography, occasionally leaving large portions of the intrahepatic ducts unexamined. Finally, CT and ultrasonography can depict complications of sclerosing cholangitis, such as cirrhosis and portal hypertension, and soft tissue masses associated with cholangiocarcinoma.¹⁴⁹ Magnetic resonance cholangiopancreatography (MRCP) is the best noninvasive means of establishing the diagnosis.¹⁴⁹ Patients with ulcerative colitis and sclerosing cholangitis are at greater risk for developing cholangiocarcinoma and secondary biliary cirrhosis.

Liver Abscess

Hepatic abscess is an uncommon complication of Crohn's disease. In one institution, they accounted for 8% of all liver abscesses.^{2,4,150} They usually develop in patients with longstanding disease but may occur as the initial manifestation of Crohn's disease.^{2,4,150} Corticosteroids and other immunosuppressive agents, perforation, intra-abdominal abscess, and anastomotic leaks are all predisposing factors to the development of a hepatic abscess in patients with Crohn's disease.^{2,4,150}

PANCREATIC COMPLICATIONS

Of patients with Crohn's disease, 1% to 2% develop pancreatitis from a variety of causes: (1) drugs such as corticosteroids, azathioprine, and metronidazole; (2) choledocholithiasis; (3) fistula from the adjacent gut; (4) sclerosing cholangitis; (5) dysfunction of the sphincter of Oddi or stenosis of the descending duodenum, leading to obstruction of the duct or

Figure 57-31 Sclerosing cholangitis. Axial T2-weighted MR images shows focal dilation of intrahepatic bile ducts in two areas (arrows). **B.** MRCP image shows multifocal strictures and irregularity of the intrahepatic bile ducts.

reflux of duodenal contents into the duct; and (6) autoantibodies against pancreatic acinar cells. Regardless of the cause, cross-sectional imaging is needed to help confirm the diagnosis of pancreatitis and, more importantly, its complications.¹⁵¹

URINARY TRACT COMPLICATIONS

Nephrolithiasis

Of patients with Crohn's disease, 2% to 10% develop nephrolithiasis as a result of water and electrolyte losses from diarrhea, malabsorption, and large ileostomy output. Oxalate stones are most common and, because they are not calcified, they may not be visible using conventional radiologic techniques.^{152,153} Non-contrast CT scans and, to a lesser degree, ultrasonography detect these stones more readily.

Hydronephrosis

Hydronephrosis may develop in patients with Crohn's disease for a variety of reasons, including calculous disease or obstruction resulting from the inflammatory effect of an abscess or phlegmon or the mass effect of creeping fat of the mesentery.^{152,153} CT is useful in detecting the hydronephrosis and obstructing mass.

Fistulas

Fistulas may develop between diseased gut and the kidney in patients with Crohn's disease, leading to a renal or perinephric abscess.^{2,4,6} Usually, enterovesical fistulas develop. Although these fistulas should first be evaluated with conventional barium studies, excretory urography, and cystography, the origin of the fistula may be edematous and prevent contrast opacification, and tiny fistulous tracts may not be seen. Conventional studies detect fewer than 50% of enterovesical fistulas; CT has an almost 90% success rate.¹⁵⁰ CT scans are initially obtained with only oral and rectal contrast administration. The presence of gas and small amounts of contrast material entering through the fistula may be obscured if the bladder is opacified after the IV injection of iodinated contrast medium.

MUSCULOSKELETAL COMPLICATIONS

Arthropathy

Arthritis is one of the most common extraintestinal manifestations of IBD; it is manifested as a peripheral arthritis or sacroiliitis-spondylitis.¹⁵⁴⁻¹⁵⁹ The radiologic findings of peripheral enteropathic arthritis are usually minimal and best seen, if at all, with conventional radiographs. The changes in the axial skeleton, affecting 3% to 16% of patients with IBD, are similar to those of ankylosing spondylitis.¹⁵⁴⁻¹⁵⁸ CT and MRI can often detect the subtle changes of early sacroiliitis before they become apparent on radiographs—bilateral, usually symmetric joint narrowing with osseous erosions followed by sclerosis are more pronounced on the iliac side of the articulation.¹⁵⁴⁻¹⁵⁸ Eventually, bony ankylosis occurs. T1-weighted fat-suppression images are superior at demonstrating the cortical erosion and subchondral sclerosis of sacroiliitis.

Avascular Necrosis

Osteonecrosis is a rare complication of IBD and usually occurs in the following clinical settings: during or after corticosteroid therapy; during TPN, especially with lipid emulsions; and most recently as a direct complication of the disease, without other precipitating factors.¹⁵⁴⁻¹⁵⁸

MRI is the best technique for establishing this diagnosis, with a reported sensitivity of 97% and specificity of 98%.¹⁵⁴⁻¹⁵⁸ On T1-weighted images, areas of low signal intensity may be seen beneath the articular surface. Alternatively, bands of low signal intensity are seen surrounding a central area of higher signal intensity. On T2-weighted images, areas of low signal intensity can become bright, and regions of high signal intensity remain high.

Asymptomatic and radiologically normal hips may have early signs of avascular necrosis on CT studies. These include subtle alterations in trabecular pattern, joint space integrity, and femoral head and acetabular contour, which may be undetected or ill-defined on radiographs.

Osteomyelitis and Septic Arthritis

Septic arthritis of the hip can complicate a psoas or retroperitoneal abscess tracking through the greater sciatic notch. MRI and CT show these changes before their recognition on radiographs.

The iliac bone and sacrum are the most frequent sites of osteomyelitis in patients with Crohn's disease. They are almost invariably the result of an adjacent pelvic abscess or enteric fistula. Accordingly, osteomyelitis is usually diagnosed on cross-sectional imaging when the abscess is identified. CT findings in osteomyelitis include cortical bone destruction, intraosseous gas, increased attenuation of the bone marrow, narrowing of the medullary cavity, serpentine drainage tracts, and the presence of an involucrum or sequestrum. With MRI, the marrow space of the involved bone demonstrates decreased signal on T1-weighted images and increased signal on T2-weighted images. Cortical destruction or thickening and edema or abscess formation in the soft tissues can also be demonstrated on MRI.

Spinal epidural abscess has been reported from fistulization of a presacral or psoas abscess in patients with Crohn's disease. Prevertebral, intraforaminal, and epidural gas may be seen on CT and MRI studies.

Osteoporosis

Osteoporosis is a common complication of IBD. Osteoporosis and osteomalacia occur secondary to malabsorption with resultant calcium and vitamin D deficiency and can also be related to corticosteroid therapy.

Psoas Abscess

Crohn's disease complications now account for 73% of all psoas abscesses.^{36,160} On the right, a psoas abscess may develop secondary to terminal ileal disease and, on the left, it can result from sigmoid or jejunal involvement. Most patients with psoas abscess have well-established Crohn's disease, but the clinical manifestations may be nonspecific. Occasionally, psoas abscess may be seen at the initial presentation of disease. CT has emerged as the single best examination for its diagnosis. CT can also direct percutaneous abscess drainage in these patients.¹⁶¹ Primary rectus sheath abscesses have also been reported as a complication of Crohn's disease and may be visualized with CT, MRI, or ultrasonography.

PULMONARY COMPLICATIONS

Although clinically significant, pulmonary manifestations are uncommon in patients with IBD. Prospective studies have identified pulmonary abnormalities in 30% to 50% of cases. There are four major clinicopathologic categories of disease: (1) airway disease (chronic bronchitis, bronchiectasis, bronchiolitis); (2) interstitial lung disease (bronchiolitis obliterans, interstitial lung disease); (3) necrobiotic nodules; and (4) serositis. Respiratory or pleuropericardial disease is much more common in ulcerative colitis than in Crohn's disease.¹⁻⁶

Differential Diagnosis of Colitis

Ulcerative colitis and Crohn's disease are responsible for most cases of enterocolitis in North America and Europe. However, infectious enteritis and colitis have been occurring more

frequently because of increased global travel and immigration, the indiscriminate use of antibiotics, and more widespread immunosuppression resulting from the large numbers of those infected by HIV, chemotherapy, and bone marrow, stem cell, and organ transplantation.¹⁻¹² Because the small bowel and colon have only a limited variety of response to a wide variety of insults, it is not surprising that the infectious enterocolitides often simulate the radiologic (Table 57-3) and clinical (Table 57-4) features of IBD. The definitive diagnosis of infectious or idiopathic IBD ultimately rests on histologic and bacteriologic documentation.

The differentiation of Crohn's colitis and ulcerative colitis is important because each disease has different therapeutic and prognostic implications. Patients with ulcerative colitis have a higher risk of developing cancer. They can also have a curative colectomy and are candidates for sphincter-preserving surgery. Patients with Crohn's disease are not candidates for ileal reservoirs because disease may recur in the ileum. The following double-contrast barium enema features enable the correct diagnosis to be made in most patients:

- 1. Ulcerative colitis is a contiguous, confluent, circumferential, and symmetric disease that begins in the rectum and extends proximally.

TABLE 57-3 Inflammatory Bowel Disease: Radiologic Differential Diagnosis		
Feature	Commonly Found In	May Occur In
Granular mucosa	Ulcerative colitis	Early Crohn's colitis (rare)
Ulceration	Crohn's colitis	Amebiasis
Discrete	<i>Yersinia</i> infection	Ischemia
	Behçet's disease	Tuberculosis
	Ulcerative colitis	Crohn's disease

Adapted from Osterman MT, Lichtenstein GR: Ulcerative colitis. In Feldman M, Friedman LS, Branch LJ (eds): *Gastrointestinal and Liver Disease*, 8th ed. Philadelphia, Saunders, 2010, pp 1975–2090.

- Crohn's disease is a patchy, discontinuous disease with asymmetric involvement that can lead to pseudodiverticula.
- The following types of ulcerations are characteristic of Crohn's disease: aphthoid, discrete, deep (>3 mm), fissuring, and rose thorn.

- Granular mucosa is typical in ulcerative colitis but not in Crohn's colitis.
- Severe anal and perianal disease is characteristic of Crohn's disease but is exceptionally rare in ulcerative colitis.
- Spontaneous fistula and sinus tracts are a hallmark of Crohn's disease.

Certain CT findings can help differentiate granulomatous and ulcerative colitis. Mural stratification is seen in 61% of patients with chronic ulcerative colitis but in only 8% of patients with chronic granulomatous colitis. Also, mean colon wall thickness in chronic ulcerative colitis is 7.8 mm, significantly smaller than that observed in Crohn's colitis (11 mm). Finally, the outer contour of the thickened colonic wall is smooth and regular in 95% of ulcerative colitis cases, whereas serosal and outer mural irregularities are present in 80% of granulomatous colitis patients.

Differentiation between these two diseases can be made on radiologic grounds in 90% to 95% of patients. The distinction is easier to make in the early stages of disease because the early manifestations are particularly distinctive. When the disease is chronic or when there have been numerous exacerbations and remissions, the distinction may be more difficult. For example, ulcerative colitis in remission may become discontinuous, whereas granulomatous colitis may involve the entire colon.^{1-6,162}

Summary

The radiologic diagnosis of ulcerative colitis and Crohn's disease is challenging. It embraces a variety of examination techniques that must be performed and interpreted with care if the radiologist is to make a significant contribution to patient management. An understanding of the anatomic and pathophysiologic basis of the radiologic features of IBD is important to appreciate the natural history and differentiating features of these perplexing diseases fully.¹⁶³⁻¹⁶⁵

Other Inflammatory Conditions of the Colon

RICHARD M. GORE | SETH N. GLICK | ALEKSANDAR M. IVANOVIC

CHAPTER OUTLINE

Bacterial Infections

Salmonellosis
Shigellosis
Campylobacteriosis
Yersinia Enterocolitis
Colitis Caused by *Escherichia coli* O157:H7
Tuberculosis
Actinomycosis

Viral Infections

Parasitic Infections

Anisakiasis
Amebiasis
Schistosomiasis
Strongyloidiasis
Trichuriasis

Fungal Infections

Histoplasmosis
Mucormycosis

Noninfectious Colitis

Nonspecific Ulcer
Microscopic (Collagenous) Colitis
Eosinophilic Colitis
Graft-Versus-Host Disease
Retractile Mesenteritis
Reactive Inflammation

Neutrophil and Macrophage Dysfunction

Chronic Granulomatous Disease of Childhood
Glycogen Storage Disease
Malacoplakia

Exogenous Causes of Colitis

Caustic Colitis
Typhlitis (Neutropenic Colitis)
Clostridium difficile Colitis

Infectious and inflammatory disorder of the colon are common and do not require imaging in most cases. In some disorders, imaging has a role in establishing the diagnosis, assessing the severity of the process, monitoring the course of the disease, and determining the presence of complications.

Bacterial Infections

Infectious colitis may be caused by bacterial, viral, fungal, and parasitic organisms.¹⁻⁴ In Western countries, bacterial colitis

represents the most common form of colonic infection, whereas in underdeveloped countries, parasitic infestation occurs most frequently. Imaging studies are not usually performed for patients with bacterial colitis because the diagnosis is readily established with routine stool cultures.

The diagnosis of bacterial colitis should be suggested by the typical presentation of acute onset of dysenteric symptoms, consisting of fever, crampy abdominal pain and tenderness (with or without vomiting), tenesmus, and small-volume diarrhea (frequently bloody). In most cases, the disease is self-limited. Routine cultures may occasionally yield false-negative results, so specialized cultures are required to isolate specific organisms.

SALMONELLOSIS

Salmonella is a gram-negative rod that is ingested with contaminated food or water.¹⁻⁴ Colonic involvement may occur during the course of typhoid fever or as an acute dysentery. Typhoid fever is caused by *Salmonella typhi* or *Salmonella paratyphi*. Presenting symptoms include marked pyrexia, arthralgias, malaise, headaches, and right lower quadrant pain. The organism initially involves the reticuloendothelial system, particularly the spleen, mesenteric lymph nodes, and Peyer patches of the terminal ileum. Splenomegaly may occur after 1 week. Gastrointestinal involvement occurs in the second or third week in approximately 50% of cases, but is obscured by other symptoms. Right lower quadrant pain and tenderness are the most common findings. When colonic involvement is present, the barium enema may reveal narrowing and loss of haustration in the cecum caused by edema and spasm, as well as ileal fold thickening and ulceration. Aphthoid ulcers in the ascending colon have also been reported.⁵ The ileum is invariably involved. Hemorrhage and perforation occur in 1% to 3% of cases. Symptoms begin to resolve in the fourth week, but relapses are common. Blood cultures are positive during the first week in 90% of patients, and the organism may be isolated from stool cultures during the second and third weeks. Chloramphenicol is the treatment of choice.

In most reported cases, barium enemas have revealed a pancolitis with loss of haustration, often associated with superficial or even deep, so-called collar button ulcers.^{6,7} Thumbprinting has also been reported. Other patients may have extensive small bowel thickening and effacement associated with a pancolitis. Double-contrast studies may reveal punctate mucosal stippling, discrete superficial ulcers, or mucosal granularity. The descending and sigmoid colon are usually involved, with variable proximal extension. Although the rectum generally appears spared radiographically, there may be mild inflammation at endoscopy.⁸ A segmental ulcerating colitis in the left colon is rare.⁹

Fulminant disease and even toxic megacolon may occur, particularly in older or debilitated persons. Bacteremia is common, and the infection may spread to the gallbladder, bones, lungs, and kidneys.

SHIGELLOSIS

Infection with *Shigella*, a gram-negative rod, may be caused by three species—*Shigella flexneri*, *Shigella dysenteriae*, and *Shigella sonnei*.¹⁻⁴ In the United States, *S. sonnei* is the offending organism in 70% of cases, whereas in Mexico and Asia, *S. dysenteriae* is most common. As with salmonellosis, infection may occur in outbreaks, particularly in warm weather. The incubation period is 1 to 3 days, and the presentation is usually similar to that of *Salmonella* infection. However, shigellosis produces a toxin that causes increased small bowel secretion and watery diarrhea, which lasts several days and then progresses to dysenteric symptoms. Systemic absorption of the toxin may also cause arthritis, pneumonitis, seizures, peripheral neuropathy, microangiopathy, and hemolytic-uremic syndrome. Bacteremia is rare but may cause vascular collapse. Stool cultures are positive within 1 day of onset and may remain positive for months. Toxic megacolon has also been reported. The disease is usually self-limited, lasting 7 to 10 days, but occasionally as long as 1 month. The mortality rate is 10% to 20% in immunocompromised patients or in patients with bacteremia.

Sigmoidoscopy almost always reveals an inflammatory process simulating ulcerative colitis; it varies from mild granularity and erythema to ulceration.^{10,11} Ulceration is more commonly seen than in salmonellosis. Ulcers are usually superficial and of varying size and shape. They are predominantly stellate but may be linear, serpiginous, or aphthoid and are superimposed on a diffusely friable mucosa. In patients with *S. dysenteriae* infection, the ulcerative phase is most marked in the second and third weeks of the disease, with erythema and edema more prominent in the first week.¹¹ In many cases, the ulceration is most severe distal to the splenic flexure. Healing ensues with gradually decreasing erythema. The process is initially continuous and pancolonic. During recovery, involvement may become patchy. Although healing is usually complete, some patients may have residual strictures, inflammatory polyps, or even persistent colitis.¹²

Barium enema reveals a predominantly left-sided colitis with deep ulcers, which may have a collar button appearance.⁷ Aphthoid ulcers may also be seen.

CAMPYLOBACTERIOSIS

Campylobacter is the most common cause of bacterial colitis. This organism has been isolated in 7% to 10% of stool cultures obtained from patients with diarrhea.¹⁻⁴ The offending agent is *Campylobacter fetus* subspecies *jejuni*. The disease is usually self-limited, lasting less than 7 days, but symptoms may persist as long as 1 month. In some cases, barium enemas reveal a pancolitis with diffuse granularity and loss of haustration simulating ulcerative colitis, whereas in others, barium enemas have revealed aphthoid ulcers, resembling those of Crohn's disease.¹³⁻¹⁶ The left side of the colon is almost always involved. Hemorrhage, perforation, and toxic megacolon have also been reported as complications. The diagnosis requires culture on selective media; serologic studies may also be helpful for confirmation.

YERSINIA ENTEROCOLITIS

Infection by *Yersinia enterocolitica*, a gram-negative rod, tends to be more common in certain regions, such as Japan, Canada, and Scandinavia.^{1-4,17-20} Specific strains may be endemic to each of these locations, and these strains have different clinical and pathologic manifestations. Patients younger than 5 years usually present with acute right lower quadrant pain and fever, simulating appendicitis. In contrast, adults may present with acute or protracted fever, pain, and diarrhea evolving over a 4- to 6-week period. Other patients may have associated arthralgias, arthritis, or rashes, such as erythema nodosum or erythema multiforme.

The terminal ileum is invariably involved on barium enemas; the radiographic findings depend on the stage of the disease.¹⁷ The most common findings include small nodules caused by enlarged lymphoid follicles or discrete punctate, aphthoid, or larger oval ulcers. Folds may also be thickened but, unlike in Crohn's disease, stenosis is not a feature. Colonic changes are manifested by aphthoid ulcers that are predominantly located in the right side of the colon, but left-sided colonic involvement is occasionally noted.²⁰⁻²² The evolution and resolution of these clinical and radiologic abnormalities may require several months. Perforation is rare, but hepatic abscess and septicemia are well-documented complications. Diagnosis requires special culture media or serologic studies. Although no treatment has been proved to be effective, the diagnosis of *Yersinia enterocolitica* is important primarily for the purpose of excluding other entities.

COLITIS CAUSED BY *ESCHERICHIA COLI* O157:H7

Escherichia coli strains are the most common cause of traveler's diarrhea and are usually self-limited. However, the subtype *E. coli* O157:H7 has drawn increased attention because it is associated with a high morbidity and mortality. Outbreaks of this infection have been noted in Canada; residents of nursing homes have been particularly susceptible. Patients typically present with watery diarrhea (without fever) that progresses over several days to a hemorrhagic colitis. The most serious complication, the hemolytic-uremic syndrome, results from a toxin associated with this infection. The overall mortality may be as high as 33%. The findings on barium enemas are similar to those of ischemic colitis, with thumbprinting, narrowing, and spasm of the involved bowel. Computed tomography (CT) may reveal low-density thickening of the wall caused by edema (Fig. 58-1). Most reported cases have involved the transverse colon, often associated with extension to the right, left, or both sides of the colon.²³⁻²⁵ The morphologic changes are caused predominantly by ischemia, and histologic specimens may resemble pseudomembranous colitis. Treatment is supportive, but this diagnosis is important so that isolation procedures can be instituted.

TUBERCULOSIS

Although once considered rare in Western countries, tuberculosis has been increasing in incidence. As a result, reports of gastrointestinal tract involvement have become more common. Patients with AIDS have been noted to be at greater risk than the general population.²⁶ Although most cases are secondary to

a pulmonary source, most patients have no evidence of active or previous pulmonary tuberculosis on chest radiographs. In endemic areas of Asia, most cases of gastrointestinal tuberculosis are caused by ingestion of the bovine bacillus. Colonic involvement is often associated with ileal disease.

Barium studies may reveal abnormalities in the ascending and proximal transverse colon that are indistinguishable from those of Crohn's disease.²⁶ It has been suggested that certain abnormalities are characteristic, such as oval or circumferential transverse ulcers, loss of anatomic demarcation between the ileum and the right colon (Stierlin sign), and a right-angle intersection between the ileum and cecum, with marked hypertrophy of the ileocecal valve (Fleischner's sign). These findings result from the exuberant mural thickening, which tends to be greater than that in Crohn's disease. Other suggestive features include extremely short segments of involvement of the ileum or cecum, markedly enlarged lymph nodes, particularly with low density on CT, and ascites. However, the most frequent findings include some combination of narrowing, deep ulceration, and mucosal granulation with nodularity and inflammatory polyps. Less common findings include aphthous ulcers, diffuse colitis, segmental colitis distal to the hepatic flexure, and short strictures, simulating carcinoma.²⁷⁻³³ Fistulas and sinus tracts are also rare.

The diagnosis can be made on endoscopic biopsy specimens that reveal caseating granulomas or positive cultures for the acid-fast bacilli.³⁴ However, the yield from endoscopy has been variable. As a result, surgical specimens are sometimes required for a definitive diagnosis. Tuberculous colitis is an important diagnosis because of the potentially catastrophic consequences of administering corticosteroids to these patients because of a mistaken diagnosis of inflammatory bowel disease.

Figure 58-1 Colitis caused by *Escherichia coli* O157:H7. Coronal reformatted CT scan shows marked mural thickening of a redundant sigmoid colon associated with submucosal edema, inflammatory change in the adjacent mesentery, and ascites.

ACTINOMYCOSIS

Actinomyces israelii is an anaerobic bacterium that occurs as part of the normal flora of the bowel but, when there is contact with tissues not normally exposed to this organism, a pathologic process ensues. Gastrointestinal involvement occurs after infection of mesenteric and peritoneal tissues from penetrating trauma, abdominal surgery, or long-standing intrauterine devices. These patients may develop inflammatory masses and fistulas that involve the colon. Presenting symptoms include a palpable mass, vague abdominal pain, and diarrhea.

Barium enemas may reveal extrinsic masses involving the colon with reactive changes, distortion, and strictures, with or without fistula formation.^{35,36} Fistulas can extend to the skin, where characteristic colonies of sulfur granules may be identified. The ileocecal region is the most common site of gastrointestinal involvement. Many of these patients have a history of prior appendectomy. In contrast, the rectosigmoid colon is the usual site of involvement in patients with intrauterine devices. Ultrasonography and CT may also reveal large inflammatory masses. Surgery is often necessary for a definitive diagnosis and for differentiating these inflammatory masses from neoplasms.

Viral Infections

Cytomegalovirus (CMV) infection is a frequent complication of AIDS; the gastrointestinal tract may be focally or diffusely involved. Gastrointestinal abnormalities are thought to result from CMV-induced ischemic vasculitis. When colonic involvement by CMV is suspected, the diagnosis can be confirmed by the presence of characteristic intranuclear inclusions (viral inclusion bodies) on endoscopic brushings or biopsy specimens.

CMV colitis usually involves the cecum and proximal colon, sometimes extending into the distal ileum. Early disease is manifested by diffuse nodular lymphoid hyperplasia. Positive cultures from the colon are diagnostic. With moderate disease, barium enemas may reveal multifocal ulcerations, appearing as shallow, well-defined ulcers scattered on an otherwise normal background mucosa.³⁷ More advanced disease (Fig. 58-2) may

Figure 58-2 Cytomegalovirus (CMV) colitis. CT scan demonstrates severe mural thickening of the transverse colon in this patient with AIDS. Note the edematous low-density submucosa, with enhancement of the mucosa and serosa.

be manifested by deeper ulcers and marked thickening of the colonic wall on barium studies and with CT.³⁷ Some patients have a pancolitis with diffuse, contiguous involvement of bowel. With bolus injection of contrast material, CT may reveal enhancement of the mucosa and serosa with hypodense thickening of the intervening bowel wall caused by edema. With severe disease, however, the bowel wall may have increased attenuation, reflecting a hemorrhagic component of this process. Hemorrhagic CMV colitis can be fatal in patients with AIDS.

Parasitic Infections

ANISAKIASIS

Within 12 to 24 hours after the ingestion of raw fish, infestation by larvae of the nematode *Anisakis* can produce severe abdominal pain, sometimes accompanied by fever, nausea and vomiting, and/or diarrhea.³⁸⁻⁴⁰ Anisakiasis has a predilection for the stomach and small intestine, but the colon may occasionally be involved by this infection. Eosinophilia is not often present in the serum but is invariably identified on biopsy specimens. The ascending colon and, less commonly, the transverse colon are involved; barium enemas may reveal segmental thumbprinting of the affected bowel. The diagnosis of anisakiasis can be suggested when double-contrast barium enemas show the actual larvae as thin, linear filling defects 12 to 20 mm long and 0.7 mm wide at the proximal portion of the diseased segment of bowel.⁴⁰ Serologic studies may be performed to confirm the diagnosis. The worm is present in the stool in less than 25% of cases. The process is self-limited, usually lasting 7 to 10 days.

AMEBIASIS

Colonic amebiasis is rare in the United States. The cysts are ingested and subsequently develop into the invasive trophozoite. This organism is harbored by 20% of the world population. Infestation by this protozoan may vary from the carrier state to fulminant colitis, and symptoms may be indolent or acute. Spread to the liver and then the lungs may result in abscesses in either of these organs.

Colonic amebiasis is usually an acute ulcerative colitis (95%) manifested by skip lesions, although the intervening bowel may be involved to a much lesser extent.⁴¹⁻⁴³ At times, the affected bowel is characterized by short regions of involvement with marked granulation (ameboma).⁴⁴ Such amebomas are seen in approximately 10% of cases and are usually located in the right side of the colon. Although diffuse colitis is not unusual, the right side of the colon tends to be more severely involved. Barium enemas usually reveal deep ulcers or bowel wall edema, but some patients may have aphthous ulcers, discrete ulcers appearing as marginal defects, or granularity with barium flecks.⁴⁵ The terminal ileum is invariably spared. The coned cecum is a suggestive but nonspecific finding. Residual deformity and stricture formation may occur, even after appropriate therapy.⁴⁶ Less than 1% of patients present with toxic megacolon, and approximately 3% present with typhloappendicitis.

The diagnosis of amebiasis is usually established by the presence of trophozoites in the stool or on rectal smear. Serologic studies are also sensitive. When amebiasis is suspected, trial therapy may be warranted, even if the diagnosis is not

confirmed; the disease may progress rapidly if these patients are inappropriately treated with corticosteroids for presumed inflammatory bowel disease.

SCHISTOSOMIASIS

Schistosomiasis belongs to the trematode or fluke group of worms; different strains are endemic to specific geographic areas. *Schistosoma mansoni* is found in the United States, Puerto Rico, and the tropics.³ *Schistosoma haematobium* is the primary form in Africa and southern Asia, and *Schistosoma japonicum* usually occurs in eastern Asia. Mixed infection with *S. mansoni* and *S. haematobium* is not uncommon, particularly in Egypt. The larva penetrates the skin, where it enters the systemic circulation. It eventually reaches the liver and matures into the adult form. Upstream migration occurs through the portal venous system to the colon, where the worms invade the bowel wall and lay eggs. Portal hypertension with secondary hepatosplenomegaly is frequently associated. Although some patients may develop a pancolitis, *S. mansoni* has a predilection for the inferior mesenteric vein and left side of the colon, *S. japonicum* infects the superior mesenteric vein and right side of the colon and terminal ileum, and *S. haematobium* infects the hemorrhoidal veins and rectum and urinary tract. Most patients present with bloody diarrhea, but some may have chronic abdominal pain, intermittent diarrhea, and a palpable abdominal mass.

Barium enema examinations may reveal nonspecific colitis involving a variable extent of colon, with narrowing, loss of haustration, and ulceration.⁴⁶ However, a hallmark of this disease is the presence of inflammatory polyps as a result of granulation reaction to the deposition of eggs in the bowel wall.^{47,48} Another suggestive finding is calcification of the bowel wall or liver, which is usually associated with *S. haematobium* but also with *S. japonicum*.^{48,49} CT is particularly sensitive to these changes. The diagnosis can be established by demonstrating the eggs in biopsy specimens or in the stool. Eosinophilia is frequently present.

STRONGYLOIDIASIS

The nematode *Strongyloides stercoralis* also gains entrance through the skin. It spreads to the lungs, ruptures into the tracheobronchial tree, and is subsequently ingested. The primary sites of involvement are the stomach, duodenum, and proximal small bowel; and a chronic host-parasite relationship ensues. In most cases, eggs are passed into the stool. However, in patients with decreased immunity, the eggs progress to the filariform larval stage and invade the portal system, producing a repeated cycle or autoinfection. The excess parasite load results in a distal accumulation of filariform larvae with subsequent colonic involvement. Because of the setting of severe debilitation, this process is often fatal. Barium enemas typically reveal findings of a diffuse ulcerative colitis.⁵⁰⁻⁵² Aphthoid ulcers may be identified in the colon.⁵³ Fistulas and sinus tracts may also be present. Eosinophilia is the rule, but the diagnosis requires identification of cysts, larvae, or both, in the stool.

TRICHURIASIS

The whipworm *Trichuris trichiura* predominantly involves children in tropical areas. The worm is minimally invasive

but invades the mucosa, with resultant bleeding, anemia, diarrhea, malaise, and cramps. Intussusception and rectal prolapse are common; the adherent worms serve as the lead point for this intussusception. Eosinophilia is usually present. The barium enema shows clumping and granularity of the barium because of excessive production of mucus.^{54,55} The worms are identified as wavy, linear lucencies 3 to 5 cm in length, sometimes terminating in a ring shape, with a central barium collection.

Fungal Infections

HISTOPLASMOSIS

Histoplasma capsulatum is a fungus endemic to river basin areas. The lung and skin are the usual sites of involvement, but the gastrointestinal tract may also be involved.⁵⁶ Gastrointestinal disease usually occurs in the setting of a chronic debilitating illness in which the intestinal symptoms are overlooked. Anemia and leukopenia may be present. Perforation, obstruction, or hemorrhage may direct attention to the alimentary tract. The ileocecal region is the most common site of disease. Other associated findings include mesenteric adenopathy, hepatosplenomegaly (often with calcifications), and abnormal chest radiographs. Barium studies may reveal right-sided colonic filling defects, one or more segments of nonspecific inflammation (e.g., narrowing, mucosal granulation, sinus tracts, ulcers, strictures), diffuse colitis, periceal masses simulating appendicitis, and rectal polyps.⁵⁶⁻⁵⁸ Mucosal biopsy specimens may demonstrate the fungus, which stains with methenamine silver.

MUCORMYCOSIS

Colonic involvement by mucormycosis invariably occurs in a setting of immunosuppression. The diagnosis is rarely made preoperatively, and almost all cases have been fatal. The sinuses, lungs, and central nervous system are the usual sites of involvement. Colonic involvement may be isolated or may be associated with abnormalities elsewhere in the gastrointestinal tract.^{59,60} The right side of the colon is most often affected; findings include a polypoid mass or segmental inflammation, with or without sinus tracts. Rarely, these patients may have a pancolitis.

Noninfectious Colitis

NONSPECIFIC ULCER

Nonspecific colonic ulcer is of unknown cause. More than 50% of these ulcers are located in the right side of the colon near the ileocecal valve, and approximately 20% are multiple.⁶¹ The clinical presentation can mimic that of appendicitis or even carcinoma. The ulceration may be superficial or deep and occurs on the antimesenteric border. The most common finding on barium enema is a focal mass with or without ulceration and, less commonly, a short stricture or segmental colitis.⁶¹⁻⁶⁵ CT scans may show a colonic mass with mesenteric stranding. This condition is rarely diagnosed preoperatively, but a nonspecific ulcer may be suspected when an ulcer is seen at colonoscopy and biopsy results are negative for other causes.

MICROSCOPIC (COLLAGENOUS) COLITIS

Microscopic (collagenous) colitis is a clinicopathologic entity characterized by a history of variable (but usually long) duration, intermittent or chronic watery diarrhea. This condition occurs predominantly in middle-aged and older women. Results of laboratory studies and diagnostic procedures, including endoscopy, are usually normal. The diagnosis is established by endoscopic biopsy specimens, which reveal increased lymphocytes in the surface epithelium and, in the variant, collagenous colitis, an increase in the width of the subepithelial collagen band.^{66,67}

The barium enema had generally been considered to be incapable of detecting changes of microscopic colitis, but double-contrast studies may occasionally reveal nonspecific inflammatory surface abnormalities, predominantly in the rectosigmoid region.^{68,69} In the appropriate clinical setting, microscopic colitis should therefore be considered in the differential diagnosis of these findings, and endoscopic biopsy specimens should be obtained. Sulfasalazine or corticosteroids may be of benefit for the control of symptoms.

EOSINOPHILIC COLITIS

Eosinophilic gastroenteritis is a disease of unknown cause that invariably involves the stomach or small bowel. Ascites is also common, and peripheral eosinophilia is usually present. Occasionally, the colon (particularly the right side of the colon) may be involved. Thumbprinting, spasm, and narrowing are the primary findings on barium study.⁷⁰ These findings may be reversible after treatment with corticosteroids.

GRAFT-VERSUS-HOST DISEASE

One of the complications of bone marrow transplantation is that the donor immune cells may recognize the host tissue as foreign. The small intestine is invariably involved. Barium studies may reveal mural thickening and fold thickening or complete loss of mucosal features (ribbon bowel). Some of these patients also have abnormalities involving the entire colon or, less commonly, selective right-sided colonic disease.⁷¹ The findings on barium enema are those of a nonspecific colitis (e.g., loss of haustration, spasm, ulceration) and, in some cases, a granular surface pattern. CT shows (Fig. 58-3) edema in the mesentery, small and large bowel wall thickening, and mucosal and serosal enhancement. Graft-versus-host disease and viral infection (or both conditions combined) are indistinguishable.

RETRACTILE MESENTERITIS

Retractile mesenteritis is a disease of unknown cause in which a spectrum of inflammatory and fibrotic pathologic changes occurs in the mesenteric fat but can extend to the intestinal wall. Autoimmune factors have been postulated. The patient's age may range from the second to the eighth decades of life, and there is a slight male predominance. Presenting symptoms include abdominal pain, diarrhea, and weight loss. The small bowel is the usual site of involvement, but colonic abnormalities are not uncommon. The sigmoid and transverse colon are most likely to be involved because these segments of bowel are intimately related to a mesentery.

Figure 58-3 Graft-versus-host disease. Axial contrast-enhanced CT scan shows edema in the mesentery, small and large bowel wall thickening, and mucosal and serosal enhancement.

The findings on barium enema may be secondary to ischemia as a result of occlusion of the mesenteric vessels or direct extension of the fibroinflammatory process.⁷²⁻⁷⁵ Barium studies may reveal long segments of mild to moderate narrowing with thumbprinting, strictures of variable length, and/or extrinsic masses with reactive changes on the contiguous margin of the bowel. CT is a complementary imaging study because it may demonstrate markedly increased density in the mesentery, with or without discrete, fibrotic soft tissue masses. Ultrasonography may also reveal solid masses with hypoechoic areas that resemble sarcomas, hematomas, or abscesses.⁷³ Surgery is often performed to relieve obstructive symptoms, but corticosteroid therapy may also be beneficial.

REACTIVE INFLAMMATION

Reactive inflammation may occur in the colon because of extension of primary inflammatory processes from other organs or from adjacent abscesses. The site of colonic disease closely correlates with its anatomic contiguity and mesenteric relationships with these structures. The appearance may vary from an area of extrinsic mass effect with reactive spiculation to long segments of concentric narrowing and spiculation, with or without an adjacent soft tissue mass that fixes and distorts the bowel. For example, appendicitis may involve the ascending colon or sigmoid colon (depending on the location of the appendix), whereas pancreatitis tends to involve a variable length of the transverse colon up to the junction with the descending colon (phrenocolic ligament). Pancreatitis may also cause obstruction (colon cutoff), fistula formation, necrosis and perforation, and strictures. Both these entities may simulate primary colitis with pain and diarrhea.⁷⁶ However, careful interpretation of the barium enema may allow the radiologist to suggest these possibilities, and a CT scan combined with appropriate laboratory studies may allow an accurate diagnosis. Less commonly, inflammatory disease in the kidneys produces reactive changes in the proximal descending or ascending colon, and acute cholecystitis may have a similar

effect on the proximal transverse colon, particularly on its superior border.

Neutrophil and Macrophage Dysfunction

CHRONIC GRANULOMATOUS DISEASE OF CHILDHOOD

In patients with conditions associated with neutrophil dysfunction, a colitis that may be segmental or pancolonic and indistinguishable from Crohn's disease has been reported.⁷⁷ Fistulas and sinuses may be features of this form of colitis. It occurs predominantly in the pediatric population. Chronic granulomatous disease of childhood is an inherited defect of leukocyte function characterized by the inability of phagocytes to kill catalase-positive microorganisms, resulting in multifocal abscesses and granulomas. The presence of lipid-bearing histiocytes in the mucosa is highly suggestive of this entity. Some degree of colonic involvement is common in these patients, but clinically significant colonic disease is rare. Some patients with colonic disease may have associated involvement of the stomach with narrowing of the gastric antrum.

GLYCOGEN STORAGE DISEASE

Glycogen storage disease type Ib is also associated with neutropenia and a metabolic defect in neutrophil activity. Recurrent pyogenic infections are a significant clinical problem in these patients. In the limited number of reported cases, gastrointestinal involvement has been manifested by long or short strictures involving the right side of the colon and even the terminal ileum.⁷⁸

MALACOPLAKIA

Malacoplakia is a granulomatous process that usually involves the genitourinary tract. However, the colon is the most frequent extraurinary site of involvement.⁷⁹ Distinctive macrophages that contain pathognomonic intracytoplasmic calcifications (Michaelis-Gutmann bodies) are present on biopsy specimens. The cause is unknown, but a macrophage defect is most likely. Unlike the urinary tract abnormalities, which tend to occur in older women, colonic disease shows a wide age distribution. Abnormalities may include small polyps or bulky masses occurring in a segmental or diffuse distribution. Barium studies may even reveal a diffuse nonspecific colitis resembling Crohn's disease. Rectal bleeding, diarrhea, and abdominal pain are the most frequent symptoms in these patients.

Exogenous Causes of Colitis

CAUSTIC COLITIS

Direct contact between the colorectal mucosa and caustic substances introduced into the rectum by various types of enemas may produce a colitis that is transient or results in complete mucosal sloughing, with subsequent strictures. The most common causes of caustic colitis are detergent or soapsuds enemas used as laxatives or herbal (ritual) enemas practiced in Third World countries as a form of medical therapy.⁸⁰⁻⁸³ In some cases, the injury has been thermal as a result of the high

temperature of the liquid.⁸⁴ The changes occur predominantly in the distal colon because of the route of entry. However, skip lesions or transverse and right-sided colonic alterations can occur as a result of spasm and prolonged contact. Bloody diarrhea is the usual presenting symptom. Barium studies may demonstrate thumbprinting or severe mucosal necrosis and ulceration that progresses to deformity or strictures. Some patients may require colectomy and colostomy.

A number of cases of colitis secondary to glutaraldehyde exposure have also been reported. This form of colitis occurs when disinfectant is inadequately removed from endoscopes. Radiographic findings include thumbprinting in the rectosigmoid colon on barium enema and a thickened colonic wall on CT.⁸⁵

TYPHLITIS (NEUTROPENIC COLITIS)

Typhlitis (neutropenic colitis) is a potentially fatal infection of the cecum and ascending colon caused by enteric pathogens in patients with severe immunosuppression. It is usually seen in patients with acute leukemia receiving chemotherapy but

also occurs in the setting of AIDS, aplastic anemia, multiple myeloma, or bone marrow transplantation. Bacteria, viruses, and fungi penetrate the damaged cecal mucosa and proliferate because of the profound neutropenia. There is edema and inflammation of the cecum, ascending colon, and occasionally ileum. Fever, abdominal pain, nausea, and diarrhea are presenting symptoms. Prompt diagnosis and supportive therapy with intensive antibiotics and fluids are required to prevent transmural necrosis and perforation. Surgical resection is indicated for patients with transmural necrosis, intramural perforation, abscess, or uncontrolled sepsis and gastrointestinal hemorrhage.

Because of the inherent risks of bowel perforation in performing barium enemas and colonoscopies in these critically ill patients, CT is the study of choice for typhlitis. CT demonstrates circumferential mural thickening (1 to 3 cm) of the cecum (Fig. 58-4), low-density areas within the colonic wall secondary to edema, pericolic inflammation and fluid and, in severe cases, pneumatosis. Clinically, CT is used to monitor decreases in mural thickness with therapy and detect subtle pneumoperitoneum in cases of silent perforation or necrosis.⁷⁷⁻⁸⁰

Figure 58-4 Typhlitis: CT and ultrasound features. **A, B.** Axial CT scans in two different patients with profound neutropenia depict mural thickening with submucosal edema involving the cecum. **C.** Sonogram in a different patient obtained through the right lower quadrant demonstrates marked mural thickening.

Figure 58-5 Pseudomembranous colitis: pathologic and CT findings. **A.** Surgical specimen shows whitish plaques on a background of hemorrhagic mucosa of the cecum and ascending colon. **B.** Coronal reformatted image shows marked mural thickening of a redundant sigmoid colon with enhancing mucosa and submucosal edema, the so-called accordion appearance. Ascites is also present. In a different patient, coronal reformatted images show mural thickening and submucosal edema of the ascending and descending colon (**C**) and the transverse colon (**D**).

Neutropenic colitis, also known as typhlitis when confined to the cecum, develops in profoundly immunocompromised patients, especially those with leukemia, AIDS, profound neutropenia caused by chemotherapy, or transplantation. A variety of organisms (particularly clostridia) have been isolated from surgical specimens. Presenting symptoms include fever, right lower quadrant pain, and diarrhea.

Plain radiographic findings of typhlitis include ileocecal dilation with air-fluid levels and small bowel obstruction secondary to inflammation. In severe cases, pneumatosis may develop.⁸⁶⁻⁹⁰

The most important consideration in the differential diagnosis is colitis caused by *Clostridium difficile* infection. A diagnosis of typhlitis can be made on the basis of the clinical and imaging findings only after other pathologic entities have been excluded. Surgery may be necessary in severe cases.

CLOSTRIDIUM DIFFICILE COLITIS

Pseudomembranous colitis has been encountered with increasing frequency as a nosocomial infection complicating antibiotic therapy. This potentially life-threatening disorder is caused by overgrowth of *C. difficile* and the subsequent release of a cytotoxic enterotoxin. This enterotoxin causes ulceration of the colonic mucosa and the formation of 2- to 3-mm pseudomembranes, which consist of fibrin, mucus, sloughed epithelial cells, and leukocytes. Mild cases may demonstrate only mucosal irregularity and nodularity with small plaque formation that cannot be detected radiologically. In advanced cases, there is

thickening of haustral folds, a shaggy wall contour, and mucosal plaques.⁹¹⁻⁹⁵

The diagnosis of *C. difficile* colitis should be suggested in patients on antibiotics who develop a sudden onset of watery diarrhea, often associated with fever, abdominal tenderness, and leukocytosis. Many of these patients are hospitalized, and many have had recent surgery. The onset of disease usually occurs within 2 days to 2 weeks after the introduction of antibiotic therapy, but some patients may develop symptoms as late as 8 weeks after these agents are discontinued. In these cases, the temporal relationship to antibiotics may be obscure, and a careful clinical history must be elicited.⁹¹

CT shows a colitis with mural thickening, which may be irregular or polypoid and have a shaggy endoluminal contour. The mural thickening, which is usually 1.6 to 1.8 cm, is a result of submucosal edema. Mucosal and serosal enhancement are seen following intravenous contrast administration. The haustra are also thickened and edematous, producing the accordion pattern, which is highly suggestive of pseudomembranous colitis (Fig. 58-5). This pattern consists of contrast trapped between thickened haustral folds that are aligned in a parallel fashion. This appearance can sometimes simulate that of deep ulcerations or fissures. Pericolonic stranding, ascites, pleural effusions, and subcutaneous edema are other ancillary CT findings.

Complications of untreated pseudomembranous colitis include toxic megacolon and intestinal perforation, with subsequent peritonitis. CT is also useful in monitoring the response to medical therapy with oral vancomycin and metronidazole.⁹¹⁻⁹⁵

Epidemiology

Colon cancer is a major public health problem in the United States, one of the most common significant cancers in the U.S. population, and the third most common cause of cancer mortality. It ranks third to lung and prostate cancer in men and third to lung and breast cancer in women.¹ The American Cancer Society estimates that in the year 2014 about 136,830 will be diagnosed with colorectal cancer and that about 50,340 will die of the disease.¹ The distribution of this disease varies widely throughout the world. It is common in North America, Europe, and New Zealand, but the incidence is low in South America, Africa, and Asia. The United States has one of the highest incidences of colorectal cancer in the world. However, even within the United States, the rates of occurrence vary

considerably, being higher in the North, among the urban white population, and among blacks.¹ Viewed in a personal way, U.S. adults have approximately a 1 in 20 chance of developing colorectal cancer during their lifetime and a 1 in 40 chance of dying of this disease.

Colorectal neoplasms account for about 9% of new cancer diagnoses in the United States. The incidence rates (per 100,000) have declined from a high of 71 in 1975 to 55.7 in 2004 to 2008 for men and from 54 in 1975 to 41.4 in 2004 to 2008 for women.¹ This decline was seen mostly in whites, whereas incidence rates for blacks have slightly increased. In the United States, the incidence rates among blacks are about 23% higher than in whites, whereas mortality rates in blacks are about 48% higher than in whites.¹ The decline in whites is probably because of increased screening for colon cancer and subsequent polyp removal. The lack of improvement over time in blacks may reflect historic underdiagnosis of colon cancer in blacks, racial differences in the trends in prevalence of risk factors for colon cancer, and lower access and use of recommended screening tests by blacks. Blacks are more likely to be diagnosed when the disease has spread beyond the colon but, once diagnosed, are less likely than whites to receive recommended surgical treatment and adjuvant therapy.^{2,3}

The distribution of cancer in the large bowel is of considerable importance because it affects the diagnostic approach. Approximately 50% of these cancers occur in the rectum and sigmoid colon, within reach of the short flexible sigmoidoscope (Fig. 59-1).⁴ The remainder are scattered throughout the proximal colon. Some authors suggest that there has been a shift to the right, rendering fewer cancers diagnosable by digital and short sigmoidoscopic examinations.⁵ Although the overall incidence of colorectal tumors increases with age, this increase is greatest for proximal neoplasms beyond the reach of the sigmoidoscope.⁶ Also, race and gender can independently predict the location of the cancer.⁷ Generally, more distal cancers are found in Asians than in blacks or whites. Whites have more distal cancers than blacks, and men have more distal cancers than women.

Factors Involved

DIETARY FACTORS

The wide variation and distribution of colorectal cancer throughout the world is probably related to dietary differences. In general, diets low in fiber and high in fat and animal protein (especially high and prolonged consumption of red or processed meat) are associated with a higher prevalence of colorectal cancer, which is inversely related to the incidence of gastric cancer.⁸ However, these conclusions are based on population studies, and a direct link between diet and colon cancer has not been demonstrated.¹

Figure 59-1 Double-contrast barium enema: evaluation of colon cancer. **A.** A 1-cm polyp (arrow) is demonstrated in the proximal transverse colon. **B.** Seventeen years later, the small polyp has grown into a full-blown polypoid carcinoma (arrow). **C.** In another patient, there are adenomas in the distal sigmoid (arrowhead), a polypoid carcinoma near the apex of the sigmoid, and an annular carcinoma more proximally in the sigmoid colon. (C from Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 3rd ed. Philadelphia, WB Saunders, 2000.)

HEREDITARY FACTORS

The role of heredity in colorectal cancer has been a subject of considerable interest. Heredity probably plays a role in 5% to 6% of all cases of colorectal cancer. Adenomatous polyposis coli (see Chapter 61) is transmitted by the classic mendelian dominant inheritance pattern, and almost all patients with this condition eventually develop colorectal carcinoma. They account for approximately 1% of colorectal cancers. Another 5% occur in patients with hereditary nonpolyposis colorectal cancer (HNPCC). HNPCCs are subdivided into those in which colorectal cancer is clustered in families (type I) and those in which there is a familial clustering of colorectal cancer with other malignancies, such as carcinomas of the endometrium, ovary, and breast (type II). In all these syndromes, carcinomas tend to occur in the proximal part of the colon and are found at a relatively young age.⁹

It has been suggested that an abnormality in the genetic material may be associated with the development of colorectal cancer.¹⁰ The discovery of four human mismatch repair genes

(*hMSH2*, *hMLH1*, *hPMS1*, and *hPMS2*) has provided novel insight into the genetic basis of this disease and raised the possibility of genetic diagnosis for the management of HNPCC patients and their family members.¹¹ Therefore, it may be important to perform DNA testing in families suspected of having HNPCC.¹²

RISK FACTORS

Although colorectal cancer is common in the U.S. population, several factors place individuals at higher than normal risk. These include older age, a personal or family history of colorectal polyps or cancer, certain hereditary conditions, diets high in saturated fat but low in fiber, excessive alcohol consumption, sedentary lifestyle, obesity, and inflammatory bowel disease (IBD). The onset of colorectal cancer is clearly related to age. The incidence increases markedly in those older than 50 and peaks in those about 70 years old. First-degree relatives of patients with colon cancer have a twofold to threefold increase

in cancer risk, as do patients who have previously been treated for colon cancer.

Patients with chronic ulcerative colitis have a higher incidence of colorectal cancer. The incidence starts to increase after the disease has been present for about 10 years, and approximately 10% develop cancer for every decade after 10 years of disease activity.¹³ These cancers tend to be more uniformly distributed throughout the colon, with a trend toward a more proximal location, and they often have a scirrhous appearance.¹⁴ Patients with pancolitis are predominantly affected. Sclerosing cholangitis is associated with a strong risk of developing colon cancer in patients with IBD; consumption of nonsteroidal anti-inflammatory drugs (NSAIDs) exerts a protective influence.¹⁴ The incidence, characteristics, and prognosis of colorectal carcinoma complicating Crohn's disease are similar to the features of cancer in ulcerative colitis, including young age, multiple neoplasms, long duration of disease, and more than a 50% 5-year survival rate.¹⁵

Pathogenesis

In the past, there was considerable controversy regarding the adenoma-carcinoma sequence. However, it is now believed that at least 70% of colorectal carcinomas start as benign adenomas that undergo malignant transformation (see Fig. 59-1).¹⁶ Up to 30% of cancers arise from a *de novo* sequence—that is, carcinoma developing in normal mucosa without an antecedent adenoma.¹⁵ Larger adenomas (>1 cm) pose a greater cancer risk.¹⁷ Thus, it is vital to detect and remove polypoid lesions larger than 1 cm. Their removal prevents the subsequent development of cancer. If the polyp has become a colon cancer, the earlier it is removed, the less likely it is to have spread.

Cancers that develop in patients with IBD generally arise from areas of high-grade mucosal dysplasia rather than from adenomatous polyps.¹⁸ Therefore, in the surveillance of these patients, blind biopsy specimens are often taken throughout the colon in an attempt to detect severe and persistent dysplasia.

Clinical Aspects

Colorectal cancer is a slow-growing malignancy, requiring a period of 7 to 10 years for a benign adenoma to undergo malignant transformation. Ideally, the disease should be detected before it becomes symptomatic. Colorectal cancer is sufficiently common in the Western world that routine screening is recommended. The American Cancer Society recommends that starting at age 50, men and women at average risk for developing colorectal cancer should follow one of the screening options listed below^{19,20}:

- Fecal occult blood test (FOBT) or fecal immunochemical test (FIT) every year
- Stool DNA test, interval uncertain
- Flexible sigmoidoscopy every 5 years
- FOBT or FIT every year, plus flexible sigmoidoscopy every 5 years
- Double-contrast barium enema every 5 years *or*
- Colonoscopy every 10 years
- Computed tomography colonography (CTC) every 5 years

The American College of Radiology recommends periodic (\approx every 5 years) double-contrast barium enema study,

especially for patients at higher than normal risk of developing colorectal cancer.²¹ A cost-effectiveness study of double-contrast barium enema in the screening for colorectal carcinoma has shown that the double-contrast barium enema is a cost-effective screening procedure in average-risk patients.²² The results were based on the assumption that a missed benign 10-mm adenomatous polyp could become malignant within 5 years. Recent advances with CT colonography should aid in clarifying its exact role and further expands its role in screening and diagnosing patients with colorectal polyps or cancer (see Chapters 53 and 54).²³⁻²⁵

If patients are at an increased risk for colon cancer, they should be tested at an earlier age than 50 years. In this group are patients with IBD, a personal or family history of colorectal polyps or colorectal cancer, and genetic syndromes, such as familial adenomatous polyposis (FAP) or hereditary nonpolyposis colorectal cancer.

Symptomatic colorectal cancer most often presents as bleeding. The severity of bleeding may range from the presence of occult blood in the stool to the passage of bright red blood per rectum to the development of iron deficiency anemia. The patient's symptoms are usually related to the location of the tumor. Approximately one third of carcinomas are in the rectum and can be reached by the examining finger or a rigid proctoscope. About 50% of large bowel cancers are in the left half of the colon and can be reached with the flexible sigmoidoscope. Left-sided tumors often present with bright red rectal bleeding or constipation caused by obstruction. The remaining tumors are scattered throughout the colon. Cecal carcinomas constitute about 10% of the entire group and are most likely to present as iron deficiency anemia caused by chronic blood loss. Other frequent symptoms of colorectal cancer include abdominal pain, which may be related to the development of obstruction or to tumor invasion of adjacent tissues. Patients may also present with a change in bowel habit or nonspecific symptoms, such as weight loss or fever.

Radiology and Diagnostic Methods

Radiology plays a critical role in the diagnosis and management of patients with colorectal cancer. The double-contrast barium enema may be used for screening, especially for patients who are at higher than normal risk.²² It also can be used as a primary method for diagnosing symptomatic colorectal cancer. Single-column studies should be considered for detecting complications, such as obstruction or perforation. Radiology using multidetector computed tomography (MDCT), CTC, magnetic resonance imaging (MRI), and/or transrectal ultrasound (TRUS) also plays an important role in tumor detection and staging.²³⁻²⁸ Treatment decisions are often based on results from positron emission tomography and CT (PET/CT).²⁹ Radiology has a significant role after treatment for colorectal cancer in the detection of recurrent disease, local and distant metastases, and metachronous colon tumors.

CONTRAST ENEMA

Radiologic examination of the colon can be performed with a single- or double-contrast technique. In most cases, double-contrast enema is superior for the examination of the rectum³⁰ and the detection of small lesions.³¹ In most series of double-contrast studies, polyps are demonstrated in 10% to 13% of all

patients,³² whereas in single-contrast studies, polyps are found in 7% of patients.

COLONOSCOPY

Many studies have claimed to show that colonoscopy is superior to contrast enema for the detection of polypoid lesions. However, most of these studies do not compare state of the art barium techniques with operators of similar interest and experience. There is an error rate inherent in colonoscopy. Part of this error rate derives from failure to reach the cecum in 15% of cases.³³ In addition, there are blind spots within the colon. Generally, these are behind folds or around flexures, and polyps or even large cancers in these regions can be missed (Fig. 59-2).³⁴ If there are significant radiologic-endoscopic discrepancies, they should be resolved by consensus or by further examination, and it should not be assumed that the endoscopy result was correct.^{35,36}

Colonoscopy and double-contrast enema examinations have comparable overall accuracy, with detection of approximately 90% of all polypoid lesions if the radiographic examination is performed by an experienced radiologist with special interest in gastrointestinal (GI) radiology.^{37,38} However, the cost and complications of colonoscopy are considerably higher than those for double-contrast barium enema. Colonoscopy or flexible sigmoidoscopy should always be used to evaluate suggestive findings in contrast enema studies, particularly in patients with marked diverticular disease. It should also be used for biopsy of lesions and removal of polypoid lesions.

CROSS-SECTIONAL IMAGING

CT has been used to detect and stage many tumors, including primary and recurrent colorectal neoplasms,³⁹⁻⁴¹ and has been joined by MRI,^{27,42,43} TRUS,^{28,42} scintigraphy with monoclonal antibody (MoAb) imaging,^{44,45} and PET.^{29,46,47} 3D virtual reality

Figure 59-2 Lesions missed at endoscopy identified on barium enema. **A.** There is a small sessile polyp (arrow) behind a fold at the rectosigmoid junction. This lesion was missed twice on sigmoidoscopy and was finally detected at the third sigmoidoscopic examination. **B.** A small polyp (arrow) is situated behind a fold at an area of angulation at the junction of the sigmoid and the descending colon. This polyp was missed on two colonoscopic examinations and was found on the third. **C.** Polypoid carcinoma is just proximal to the rectosigmoid junction. This lesion was missed on several sigmoidoscopic and colonoscopic examinations and was confirmed only at surgery. **D.** Polypoid carcinoma at the hepatic flexure was missed on initial colonoscopy. (**A**, **C**, and **D** from Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 3rd ed. Philadelphia, WB Saunders, 2000; **B** from Laufer I, Smith NC, Mullens JE: *The radiological demonstration of colorectal polyps undetected by endoscopy*. *Gastroenterology* 70:167-170, 1976.)

techniques, such as CTC, have been used with increasing frequency, and results are excellent.²³⁻²⁵

Few studies present an in-depth assessment of the value of the various techniques. A review of the large body of literature on this topic reveals many conflicting reports about the effectiveness of the various methods and opposing recommendations for their use. In many cases, this disagreement is because of early, overly enthusiastic conclusions about high success rates with each new imaging technique and underestimation of their pitfalls. Also, some literature reports contain incomplete proof of pathology or neglect to include all factors necessary for complete staging of colon neoplasms.

Benign Epithelial Polyps

INCIDENCE

Benign tumors of the colon are extremely common and usually do not cause symptoms. These polyps are found in 10% to 12.5% of patients studied with double-contrast techniques, and the incidence rises dramatically with increasing age (Fig. 59-3A). Polyps occur most frequently in the left colon and are scattered throughout the remainder of the transverse and right colon (see Fig. 59-3B). As people age, there is a shift in the incidence of polyps to the right side of the colon, coinciding with a shift in the distribution of colon carcinoma to the right.^{48,49}

PATHOLOGY

The term *polyp* refers only to a focal, protruded lesion within the bowel. In general terms, a polyp may be neoplastic or non-neoplastic. Most non-neoplastic polyps are inflammatory or hyperplastic. They are generally small and usually occur in the distal colon. Neoplastic polyps may represent true neoplasms of any component of the bowel wall. Epithelial neoplasms—adenomas—are the most important because they serve as precursors to colorectal carcinoma. The demonstration of a polypoid lesion on a barium enema does not necessarily provide information regarding its pathologic nature. Whenever possible, polyps larger than 1 cm in diameter must be removed, preferably by colonoscopic polypectomy (Fig. 59-4), because of the increased risk of harboring a malignancy.

Most colonic adenomas are tubular adenomas. However, tubular adenomas have various degrees of villous change and, as a polyp becomes larger, the degree of villous change increases. At the other end of the spectrum, some polyps are villous adenomas because the surface consists of frondlike structures arising from the base of the mucosa. Thus, there may be a transition from tubular adenoma to tubulovillous adenoma to villous adenoma. It has been suggested that any adenoma with more than 75% villous change should be referred to as a villous adenoma.⁵⁰ In general, the risk of carcinoma is related to the proportion of villous change in an adenoma.

In small adenomas, it may be impossible to distinguish villous change radiologically. However, as the adenoma becomes larger and the proportion of villous change increases, a reticular or granular mucosal surface may be seen (Fig. 59-5A).⁵¹ Large villous adenomas have an atypical radiologic appearance.⁵² They are large, bulky polypoid masses with barium caught between the frondlike protrusions, producing a lacy surface pattern (see Fig. 59-5B). Large villous tumors should be removed

Figure 59-3 Incidence and distribution of colorectal polyps.

A. Incidence of colonic polyps related to age (based on 800 consecutive double-contrast enemas). There is an increasing incidence of colonic polyps, ranging from 3% in those in their 20s to 26% in those in their 80s. **B.** Distribution of colorectal polyps (based on 108 consecutive polyps). Approximately 60% of the polyps are in the rectum and sigmoid colon. (**A** from Laufer I: *The double contrast enema: Myths and misconceptions*. *Gastrointest Radiol* 1:19–31, 1976, with kind permission from Springer Science and Business Media; **B** from Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 3rd ed. Philadelphia, WB Saunders, 2000.)

completely because malignant degeneration may occur in only a portion of the tumor, and random biopsy sampling is unreliable for the detection of malignant change.

Other non-neoplastic polyps may also be found in the colon. These include juvenile polyps, which may be single or multiple and may be found in adults and in children. Hamartomatous polyps are found in patients with Peutz-Jeghers syndrome and inflammatory polyps in patients with Cronkhite-Canada syndrome (see Chapter 61).

Figure 59-4 Endoscopic polypectomy. **A.** The sheath containing the snare is seen advancing toward the sigmoid polyp. **B.** Postpolypectomy appearance. **C.** Histology of tubular adenoma.

POLYP DETECTION

Barium Enema

A polyp may be demonstrated as a radiolucent filling defect, contour defect, or ring shadow because it is simply a protrusion of the mucosa into the bowel lumen (see Chapter 2). The greatest and most frequent difficulty arises in distinguishing polyps from fecal residue. In general, fecal residue is mobile and is usually found on the dependent surface in the barium pool. In addition, several features may suggest that the filling defect represents a true polyp. These include the bowler hat sign (Fig. 59-6A) and Mexican hat sign (see Fig. 59-6B). Although the bowler hat sign can also be produced by a diverticulum, the direction of the dome of the bowler hat distinguishes a polyp from a diverticulum.⁵³ When the dome of the hat points away from the axis of the bowel, the lesion is a diverticulum; when the dome points toward the lumen of the bowel, it is a polyp. Villous adenomas may have a reticular or granular surface because of barium trapped between the fronds of the tumor.⁵¹ These signs are illustrated and discussed in detail in Chapters 2 and 3. Some hyperplastic polyps may not appear as smooth sessile lesions measuring 5 mm or less, but as larger lobulated lesions that cannot be distinguished morphologically from adenomatous polyps.⁵⁴

Rubenstein and coworkers have used the term *carpet lesion* to describe a flat lobulated lesion that is manifest primarily as an alteration in the surface texture of the bowel (Fig. 59-7A).⁵⁵ These lesions may be large and are mostly tubular adenomas with varying degrees of villous change. In some cases of colorectal carcinoma, the background of a benign carpet lesion can be recognized (see Fig. 59-7B).

Cross-Sectional Imaging

Benign lesions of the colon, such as hyperplastic polyps or adenomatous polyps, are usually not examined by CT or MRI. They are demonstrated by barium examinations or by an endoscopic technique and are seen during CT or MRI examinations only incidentally. These techniques are used only if these benign tumors become large enough to have a high likelihood of harboring a malignancy. Benign polyps appear as sessile soft tissue masses that protrude into the lumen of the bowel on axial images (Fig. 59-8). They are usually detected only if the patient has undergone colonic cleansing or if the polyp is large. If the polyp is pedunculated, CT scans may demonstrate a large polypoid mass that represents the combined polyp and stalk (see Chapter 53).

Kim and colleagues⁵⁶ have suggested that villous adenomas have a characteristic CT appearance based on their high mucus

Figure 59-5 Villous adenomas. **A.** A flat tumor in the descending colon with an irregular surface suggestive of a villous adenoma. This was a villoglandular polyp. **B.** Typical villous tumor in the sigmoid colon. This tumor exhibits the typical, irregular, frondlike surface of a villous tumor. It was a malignant villous adenoma. **C.** Gross pathology specimen shows cauliflower-like colon polyp. **D.** Histology reveals frondlike nature of polyp. (**A** and **B** from Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 3rd ed. Philadelphia, WB Saunders, 2000.)

Figure 59-6 Double-contrast barium enema and colonoscopy features of polyps. **A.** The bowler hat sign representing a sessile polyp. **B.** Mexican hat sign. This is the typical appearance of a pedunculated polyp seen end-on. The outer ring represents the head of the polyp, and the inner ring represents the stalk. **C.** Endoscopic view of pedunculated polyp. (A and B from Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 3rd ed. Philadelphia, WB Saunders, 2000.)

Figure 59-7 Carpet lesions.

A. Typical carpet lesion (arrow) in the cecum. **B.** Malignant transformation in a carpet lesion. An obvious polypoid carcinoma is seen in the ascending colon. Surrounding the polypoid lesion is the mucosal change representing the underlying adenoma. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 3rd ed. Philadelphia, WB Saunders, 2000.)

Figure 59-8 CT of benign polyps. **A.** Axial thin-section MDCT scan identifies a sessile polyp (arrow) on the left wall of the proximal sigmoid colon, which was confirmed by colonoscopy in a patient with carcinoma of the cecum and familial polyposis syndrome. **B.** Axial thin-section MDCT below level shown in **A** demonstrates a second polyp (arrow) in the small bowel.

content. The CT features of villous adenomas include homogeneous water density (<10 HU) occupying more than 50% of the lesion and an eccentric location on the luminal side of the mass. No air-fluid level is seen, and the lesion should not have a round cystic configuration. Opaque oral or rectal contrast material should not be used to diagnose a suspected villous adenoma because it obscures the lesion. In these cases, insufflation of air, water, or oily substance administered per rectum may be helpful. Because of their malignant potential, larger villous adenomas should always be staged by CT or TRUS if located in the rectum.⁵⁷

On MRI scans, benign polyps appear as low-intensity structures on T1-weighted spin-echo sequences. If there are many mucin-producing cells, the signal intensity of the polypoid mass increases on T1-weighted sequences. TRUS is used for assessment of sessile polyps large enough to have an increased risk for malignancy. In these cases, TRUS can be used to determine the depth of invasion by a sessile mass that protrudes into the lumen. The depth of invasion is best assessed by TRUS because it is the only method that can demonstrate the various layers of the colonic wall. If the intraluminal component is large, false tumor measurements and erroneous depiction of the surface of the mass can occur because of compression of the tumor by the transrectal probe.

Adenocarcinoma

BARIUM ENEMA

Early Cancer

The radiologic detection of early colorectal cancer is basically an exercise in the detection of polyps. The typical early colon cancer is a flat, sessile lesion that may produce a contour defect (Fig. 59-9). Although most polyps detected radiologically should be removed if they are larger than 5 mm in diameter, a number of radiologic criteria have been used for the detection of malignancy in colorectal polyps.⁵⁸ The size of the polyp is the most important criterion. Carcinoma is very rare in polyps smaller than 5 mm. The incidence of cancer is approximately 1% in polyps in the 5- to 10-mm range (Fig. 59-10), 10% in polyps measuring between 1 and 2 cm, and more than 25% in polyps larger than 2 cm.⁵⁹

Malignant polyps tend to grow more quickly than benign polyps, although there is considerable overlap between the two

Figure 59-9 Typical early colon cancer. A 1-cm polypoid mass with a contour defect (arrow) is seen along the lateral wall. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 3rd ed. Philadelphia, WB Saunders, 2000.)

groups.⁶⁰ If there is definite evidence of polyp growth on serial examinations, malignancy should be suspected. The presence of a long thin stalk is generally a sign of a benign polyp. Rarely, these polyps harbor malignancy.⁶¹ As a rule, the stalk associated with carcinoma is short and thick (Fig. 59-11). If the head of the polyp is irregular or lobulated, the probability of malignancy is greater, although some benign polyps may have an irregular or lobulated surface.

Advanced Cancer

Most patients with symptomatic colorectal carcinoma have advanced lesions. These lesions are generally annular or polypoid tumors seen as filling defects in the barium column or as

Figure 59-10 Early colon cancers: polypoid carcinoma with a pedicle in 29-year-old man with rectal bleeding. A pedunculated polyp in the descending colon (large arrow) has a typically benign appearance. This was removed at colonoscopy and was found to be a carcinoma with invasion of the stalk. The smaller lesions (small arrows) were hyperplastic polyps. (From Laufer I: *The double contrast enema: Myths and misconceptions*. *Gastrointestinal Radiol* 1:19–31, 1976.)

Figure 59-11 Pedunculated early cancer. Early carcinoma (arrow) with a short, thick stalk. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 3rd ed. Philadelphia, WB Saunders, 2000.)

contour defects. In addition, plaquelike lesions can produce abnormal lines on double-contrast barium studies (Figs. 59-12 and 59-13).⁶² Annular or semiannular carcinomas as seen with barium enema have a higher rate of serosal invasion and lymph node metastases than polypoid carcinomas.⁶³

Advanced cancers are often associated with sentinel polyps or additional polyps elsewhere in the colon. Approximately 5% of patients who have a colon carcinoma have additional, synchronous carcinomas in the colon (see Fig. 59-13).^{59,64} Therefore, whenever possible, the entire colon should be examined, even when a carcinoma is encountered in the distal bowel. The barium enema may be used to search for neoplastic lesions larger than 1 cm in patients with incomplete colonoscopy.⁶⁵

Carcinomas are particularly difficult to detect in patients with extensive diverticular disease of the sigmoid colon (Fig. 59-14). If the radiologic examination leaves any doubt regarding the presence of a carcinoma, flexible sigmoidoscopy should be recommended to confirm or exclude lesions in the sigmoid colon.⁶⁶

Advanced carcinoma may have an atypical appearance. The linitis plastica type of carcinoma has predominant submucosal infiltration and fibrous reaction.⁶⁷ The radiologic appearance may be suggestive of an inflammatory stricture. This type of carcinoma is particularly likely to develop in patients with ulcerative colitis (see Chapter 57).

Complications

The most important complications of colorectal cancer include bleeding, bowel obstruction, and perforation. Massive rectal bleeding caused by colon carcinoma is rare; the bleeding is more often manifest as occult blood in the stool or as chronic anemia. Colorectal cancer is one of the major causes of large bowel obstruction. Obstruction may be caused by encroachment of the tumor mass on the lumen of the bowel (Fig. 59-15A). Antegrade and retrograde obstruction tend to be poorly correlated. Frequently, there is a high-grade obstruction to the retrograde flow of barium when the patient has few or no symptoms of clinical obstruction. In the case of polypoid tumors, obstruction may also be caused by colocolic intussusception (see Fig. 59-15B). In patients with long-standing obstruction and colon distention, mucosal ischemia may result in an ulcerative form of colitis affecting the colon proximal to the obstruction.

Advanced cancer may result in perforation of the colon and a pericolic abscess (Fig. 59-16A). The signs, symptoms, and radiologic features of a perforated carcinoma may be difficult to distinguish from those of a pericolic abscess associated with diverticulitis (see Fig. 59-16B). However, evidence of GI blood loss makes a malignant origin much more likely.⁶⁸ Perforation of the colon may lead to a fistula to adjacent organs, such as the

Figure 59-12 Advanced colon cancer. **A.** Annular "apple core" lesion. **B.** Large polypoid carcinoma (arrows) at the splenic flexure. **C.** Lateral view shows an ulcerated plaque-like carcinoma etched in white (arrows) at the rectosigmoid junction. **D.** Specimen shows ulcerating polypoid carcinoma. A nearly obstructing polypoid carcinoid is seen in the transverse colon, and a second adenoma is seen in the sigmoid colon. **B.** Multiple polypoid carcinomas (arrows) in the ascending colon. **C.** Specimen shows polypoid cancer (arrow) and multiple synchronous polyps. (**A** and **B** from Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 3rd ed. Philadelphia, WB Saunders, 2000.)

Figure 59-14 Carcinoma in a patient with diverticulosis. The polypoid carcinoma (arrow) is more difficult to recognize in the presence of extensive diverticulosis. (From Laufer I, Levine MS [eds]: *Double Contrast Gastrointestinal Radiology*, 3rd ed. Philadelphia, WB Saunders, 2000.)

stomach (Fig. 59-17A), duodenum (see Fig. 59-17B), bladder, or vagina. The fistulous communication can be demonstrated by barium study or by the extracolonic presence of gas or contrast medium on CT scans.

COMPUTED TOMOGRAPHY

Primary Colorectal Carcinoma

CT and endoluminal ultrasound are better suited for the evaluation of tumor stage than manual examination, barium enema, or fiberoptic techniques. In the presence of a colorectal cancer, CT and ultrasound may visualize a discrete mass (Fig. 59-18) or focal wall thickening (Fig. 59-19), but this finding is nonspecific and requires further investigation. The wall thickening may be circumferential, with or without extension beyond the bowel wall (Figs. 59-20 and 59-21A). Water introduced per rectum and multiplanar reconstructions often help delineate a tumor better (see Fig. 59-21B). Asymmetric mural thickening, with or without an irregular surface contour, is suggestive of a neoplastic process (see Fig. 59-20), particularly if benign causes can be excluded by history or physical examination. In the anorectal region, internal hemorrhoids must be distinguished from a polypoid malignancy.

With a properly distended lumen, a colonic wall thickness less than 3 mm is normal, 3 to 6 mm is indeterminate, and more than 6 mm is definitely abnormal. If the tumor is contained within the wall of the colon or rectum, the outer margins of the large bowel appear smooth. CT cannot reliably assess the depth of mural penetration. The various layers of bowel wall and depth of mural invasion can be depicted by endoluminal

Figure 59-15 Colon cancer causing bowel obstruction. **A.** An annular carcinoma in the mid-descending colon completely obstructs the retrograde flow of barium. **B.** Cecal carcinoma with colocolic intussusception extending into the midtransverse colon.

Figure 59-16 Perforated carcinoma of the colon. **A.** Barium filling of a perforation caused by recurrent carcinoma of the colon at the hepatic flexure. **B.** In another patient, a tapered narrowing in the sigmoid colon is caused by a pericolic abscess resulting from perforation of a sigmoid carcinoma. The appearance may be difficult to distinguish from that of diverticulitis.

Figure 59-17 Fistulas complicating carcinoma of the colon. **A.** Gastrocolic fistula arising from a carcinoma at the splenic flexure (arrow). **B.** A carcinoma of the transverse colon giving rise to a fistula to the duodenum (arrow).

Figure 59-18 Large intraluminal mass in a distended rectum without extension beyond bowel wall (T2N0M0). **A.** A thin-section MDCT scan in the arterial phase demonstrates a very large intraluminal mass (*large arrows*) that appears to arise from the anterior wall of the rectum. Bladder wall (*thin arrows*) is clearly separated from the rectal wall by a thin layer of fat. **B.** Several centimeters below the level of **A**, the fat plane between bladder wall (*thin arrows*) and the mass (*large arrow*) in the anterior rectal wall remains intact. **C.** Coronal MPR demonstrates the large intraluminal component of the mass (*large arrows*) and the wall thickening (*small arrows*), with a smooth outer border. **D.** The sagittal multiplanar reformatted image demonstrates a clear fat plane between the bladder wall (*small arrow*) and thickened rectal wall (*thin arrow*). Both MPRs confirm absence of perirectal infiltration. The large intraluminal mass (*large arrows*) is also appreciated.

Figure 59-19 Rectal carcinoma confined to the bowel wall (T2N0M0; Dukes' stage B1). **A.** Axial thin-section (2.5 mm) MDCT scan of the rectum in the arterial phase and with rectal administration of water demonstrates focal thickening of the anterior and right lateral rectal wall (long arrows). The outer margin of the rectum is smooth and well preserved. The rectal tube also is seen (arrowhead). No abnormal lymph nodes are identified (CT stage II). **B.** Axial MDCT scan obtained with a slice thickness of 5 mm and in the portal venous phase also shows the lesion (arrows) but the outer tumor margins are ill defined and less well assessed. **C.** Rectal carcinoma with microextension into perirectal fat, T3N0M0. The wall of the distal sigmoid colon is circumferentially thickened as a result of a concentric adenocarcinoma, and its outer margins are smooth. No adenopathy or invasion of fat is demonstrated. The thickening of the rectal wall in **A** and **C** appears similar on CT but represents different depths of tumor infiltration.

ultrasound or MRI with endorectal coils. These techniques can also determine the layer from which the tumor arises, which is important for differentiating an adenocarcinoma from a lymphoma or GI stromal tumor.

Tumor invasion beyond the bowel wall is suggested by a mass with nodular or spiculated borders, associated with strands of soft tissue extending from the muscularis propria into the perirectal fat or from the serosal surface into the pericolic fat (Fig. 59-22). Broad-based soft tissue extensions from the tumor into the perirectal fat are more indicative of tumor extension than spiculation, which often represents a desmoplastic reaction. Desmoplastic reaction frequently leads to overstaging by MRI because it can be difficult to distinguish between fibrosis alone and fibrosis that contains tumor cells (Fig. 59-23).⁴² Extracolonic tumor spread is also suggested by loss of tissue fat planes between the large bowel and surrounding muscles, such as the obturator internus, piriformis (Fig. 59-24), levator ani, puborectalis, coccygeal, and gluteus

maximus. Invasion is definite only when a tumor mass extends directly into an adjacent muscle, obliterating the fat plane and enlarging the individual muscle. Cross-sectional methods such as CT cannot detect microscopic invasion of the fat surrounding the colon or rectum (see Fig. 59-19) and tend to understage these patients. Spread to contiguous organs in the pelvis can be simulated by absence of tissue planes between the viscera and tumor mass, without actual invasion. Vascular or lymphatic congestion, inflammation, or actual absence of fat because of severe cachexia can cause obliteration of fat planes. Therefore, invasion should be diagnosed cautiously and considered definite only if an obvious mass clearly involves an adjacent organ. Distinction between tumor infiltration of adjacent muscle and simple absence of fat separating normal structures is particularly difficult in the area of the lower rectum and anal verge.

In our experience, CT results can be improved through the use of a large, rapidly delivered bolus of intravenous (IV)

Figure 59-20 Adenocarcinoma of the rectum confined to the rectal wall with perirectal lymph nodes (T2N1M0; Duke's stage C1).
A. MDCT scan demonstrates minimal but diffuse wall thickening (red arrows). Mesorectal fascia is well shown (arrowheads). Perirectal lymph nodes (white arrows) are seen in the perirectal fat adjacent to left lateral wall of rectum. MDCT was performed after one course of radiation, which probably caused the diffuse wall thickening. **B.** MDCT scan slightly below the level in **A** reveals asymmetric nodular thickening of left lateral wall of the rectum (arrows) without extension of tumor into perirectal fat.

contrast agent and MDCT with thin sections and water as rectal and colonic contrast material (see Fig. 59-23). With this approach, the pelvis is scanned at peak enhancement, and the enhanced wall of the rectum can be better distinguished from adjacent levator ani and sphincter muscles. CT generally is used for staging and not for detection of colonic lesions. Nevertheless, ultrathin sections (0.625- to 1.25-mm slices) obtained with MDCT can facilitate the demonstration of even small lesions and increase the accuracy of tumor staging. Staging results can be further improved if multiplanar reformats are used, and interpretation is based on a combination of axial slices and multiplanar reformats (see Fig. 59-18).⁶⁹ Coronal reformats often are helpful to define the relationship of the rectal mass to the levator ani, puborectalis, and sphincter muscles, which is helpful in planning the appropriate surgery. Nevertheless, CT cannot achieve the exquisite soft tissue resolution afforded by MRI with gadolinium contrast enhancement.⁷⁰ Such superior distinction is particularly useful in the lower pelvis for assessing tumor relationship to the mesorectal fascia and invasion into muscle, nerves, bladder, and male or female organs (see later, “Magnetic Resonance Imaging”).⁷¹

Primary and recurrent colon cancer can invade the seminal vesicles, prostate, bladder, uterus (Fig. 59-25), ovaries, small bowel, and sciatic nerves and can obstruct the ureters. Occasionally, tumors of the prostate, uterus, or ovaries that invade or are contiguous with the rectum or sigmoid colon can be indistinguishable from an invasive colon neoplasm. Areas of low attenuation within the mass suggest tumor necrosis; tumor calcifications indicate a mucinous adenocarcinoma. A vesicorectal fistula manifests as air in the tract and bladder. After administration of an IV contrast agent, the wall of the tract may enhance. Alternatively, a jet of positive rectal contrast material can be identified in the bladder. Fistulous tracts can also extend

into the uterus or vagina, and sinus tracts may be seen in the fat of the ischiorectal fossa.

Colon tumors can destroy adjacent bone, usually the sacrum and coccyx. Large tumors can involve the ilium. Advanced bone invasion causes frank bone destruction often associated with a soft tissue mass. Subtle cortical destruction visible only on bone window settings may be the only manifestation of bone invasion.

Liver metastases usually appear hypodense on non-contrast-enhanced scans. Foci of calcification can be seen within primary or metastatic mucinous adenocarcinomas (Fig. 59-26). After a bolus injection of contrast material, the CT density of hepatic colonic metastasis can change rapidly. Compared with the uninvolved liver parenchyma, metastases often show early rim enhancement or become partially hyperdense (Fig. 59-27), go through an isodense phase, and then become low-density lesions again. Optimal bolus and scanning techniques are necessary to minimize false-negative results that can occur when metastases become isodense with normal liver parenchyma when scanning is extended into the equilibrium phase. This isointensity often occurs with small (<2 cm) lesions. If only one to four hepatic metastases are detected (more if they are peripheral and can be easily wedged out), and no extrahepatic disease is present, an aggressive treatment plan appears warranted, because there is improved 5-year survival after removal of isolated metastatic foci by resection or ablation.⁷²⁻⁷⁴

CT with arterial portography (CTAP) was formerly considered the single most accurate means of detecting additional metastatic lesions in the normal-appearing lobe.⁷⁵ However, the general use of CTAP has been abandoned in favor of helical CT. Helical CT can achieve similar sensitivities, has a lower false-positive rate than CTAP, and is noninvasive.^{76,77} In one helical CT study with surgical correlation in all patients, the sensitivity for detecting colonic metastases to the liver was 85% and the

Figure 59-21 Adenocarcinoma of the sigmoid colon, A, B. T3N0 M0 (Dukes' stage B2). **A.** The axial MDCT scan demonstrates a nodular mass along the left lateral wall of the sigmoid colon (arrows) without definite extension beyond the bowel wall. **B.** In the coronal reconstruction a broad based extension of tumor (arrow) into the pericolic fat is seen. **C-E.** T3N1M0 (Dukes' stage C1). **C.** The full extent of the circumferential tumor in the sigmoid colon (arrows) is best demonstrated in the coronal reconstruction. Subtle broad-based stranding (short arrow) suggests extension beyond the bowel wall. **D.** The sagittal reconstruction demonstrates a small lymph node (short arrow) next to the sigmoid neoplasm (long arrows). **E.** The true extent of the tumor (arrows) is more difficult to assess in the axial views but the metastatic lymph node (short arrow) is well shown, demonstrating the complementary nature of the various planes.

Figure 59-22 CT scan of rectal tumor with extension beyond the wall (T3N0M0; **Dukes' stage B2**). **A.** The thin-section MDCT scan in the arterial phase reveals nodular broad-based extensions of soft tissue density (arrows) into the perirectal fat indicative of tumor invasion. **B.** MDCT scan slightly below the level in **A** shows a focal mass with some spiculation (arrows). This feature is more suggestive of desmoplastic reaction without tumor cells rather than infiltration of tumor into perirectal fat. This distinction is not always possible on MDCT. **C.** The coronal MPR reveals the nodular outer surface of the tumor (arrows). **D.** The sagittal MPR does not demonstrate this feature effectively. The mass is located in posterior wall (arrow) of upper rectum.

Figure 59-23 Rectal carcinoma in posterior and lateral walls (arrows) of rectum (T3N1M0; **Dukes' stage C1**). **A.** Outer borders (arrows) are slightly irregular, but no definite nodularity can be seen. This makes it difficult to distinguish a desmoplastic reaction from actual tumor extension in this case. The patient was diagnosed by MDCT as probably a T3. **B.** At a level higher than in **A**, tumor is present only in posterior wall (thick arrow). Water facilitates visualization of intraluminal component of tumor in spite of the presence of feces. Also note hypogastric lymph nodes (thin arrow) that are lateral to mesorectal fascia.

Figure 59-24 CT scan of primary invasive rectal adenocarcinoma (T4bN2M1; Dukes' stage D). **A.** Large enhancing rectal mass (white arrow) with extension to pelvic sidewalls. Enhanced mass is inseparable from the sacrum (black arrows) and piriformis muscle (arrowhead) on left. **B.** Rectal mass (red arrow) directly extends into mesorectal fascia (long arrow). Abnormal internal iliac lymph node (small arrow) also is identified. **C.** At a level just below the midpole of kidneys, extensive retroperitoneal adenopathy (arrows) is demonstrated. **D.** Several hepatic metastases (arrows) are seen.

Figure 59-25 Sigmoid carcinoma with invasion of uterus (T4bN1M0; Dukes' stage C2). **A.** Long segmental thickening (small arrows) of sigmoid wall. Note the absence of wall stratification, which can be seen in diverticulitis. The sigmoid tumor is inseparable from the low-density mass in the uterus (large arrows). **B.** At a level 5 mm below **A**, gas (long arrow) is seen, indicating direct invasion of the tumor into uterus with perforation and necrosis. Note ascites (short arrows) along the pelvic sidewall.

positive predictive value was 96%.⁴¹ MRI with ferumoxides or gadolinium enhancement also provides excellent results in distinguishing hepatic metastases from colon carcinoma, but this technique is more expensive and not as widely available as CT.^{78,79} In one series, the MRI sensitivity for colorectal liver metastases was 96.8% but only slightly over one third of patients

underwent curative resection for histologic confirmation.⁷⁸ More recently, MRI enhanced with gadoxetate disodium (Primovist in Europe and Eovist in the United States, Bayer Pharmaceuticals) has shown excellent results for assessing hepatic metastases from colonic carcinoma and were superior to MDCT.⁸⁰ Large series are still needed to establish the true

Figure 59-26 Large mucinous sigmoid cancer (T3N1M0; Dukes' stage C2). Large sigmoid mass with pericolic fat infiltration (short arrows) and intramural calcifications (arrowheads) is identified. The transition to normal proximal sigmoid colon (long arrows) can be clearly seen.

cost-effectiveness of the various techniques. Intraoperative ultrasound is often used as the gold standard, but not all published studies had histopathologic correlation.⁴¹ In patients for whom resection is not an option, thermal tumor ablation or selective catheterization and intra-arterial chemotherapy of the liver are often used, but only if there is no evidence of tumor spread to extrahepatic sites. Local or distant adenopathy, adrenal metastases, peritoneal carcinomatosis, metastases to other areas of the GI tract, and lung metastases are some findings that preclude resection or chemoembolization of liver lesions.

Generally, rectal carcinoma metastasizes to lymph nodes along the superior rectal vessels to the mesenteric vessels for upper rectal tumors and along the middle rectal vessels to the internal iliac vessels for lower rectal tumors. Advanced low rectal or anal tumors drain along the inferior rectal vessels into the inguinal nodes. Metastases may be found in nodes in the retroperitoneum (see Fig. 59-24) and porta hepatis. In other areas of the colon, lymph node metastases follow the normal pattern of lymph drainage from the involved area. Local lymph nodes may or may not be demonstrated, depending on separability from the main mass and size of the lymph nodes (Fig. 59-28). In the abdomen and pelvis, lymph nodes more than 1.0 cm in diameter are considered abnormal. The pathologic nature of node enlargement cannot be determined absolutely by CT, although asymmetry, irregularity of the nodal margins and, less reliably, size criteria can be used to establish lymph node abnormality.⁸¹

Benign and malignant disease can produce lymphadenopathy, and often only PET or guided biopsy can provide a definitive diagnosis. Many metastatic foci are found in normal-sized lymph nodes (<1 cm) that cannot be considered abnormal by CT if size is used as the only diagnostic criterion. Pericolic lymph nodes next to a segment of thickened colonic wall are seen much more frequently in patients with colon cancer than in those with diverticulitis. Therefore, the presence of such nodes should lead to further evaluation in patients with suspected diverticulitis.⁸² Additional signs that favor a diagnosis of colon carcinoma over diverticulitis are loss of a

Figure 59-27 Nonobstructing adenocarcinoma in the splenic flexure with liver metastases (T2N0M1; Dukes' stage D). Two hepatic metastases (white arrows) are identified. The primary tumor has smooth outer margins (red arrows) and is located in the splenic flexure. The tumor was first diagnosed by MDCT and surgically confirmed to be stage T2.

normal enhancement pattern in the thickened bowel wall and absence of inflamed diverticula.⁸³ Because hyperplastic or inflammatory nodes are rare in the perirectal area, demonstration of nonenhanced, small (<1 cm), round or oval soft tissue densities suggests the presence of malignant adenopathy (Fig. 59-29).

There are certain pitfalls in the interpretation of CT scans of patients with colon tumors.⁸⁶ CT scans obtained soon after surgery or radiation therapy can demonstrate edema or hemorrhage of the pelvic structures that simulates recurrent neoplasm. Chronic radiation changes in the pelvis may be difficult or impossible to distinguish from colon tumor without CT-guided biopsies.⁸⁵⁻⁸⁸ It is therefore essential to determine the tumor stage by CT or MRI before the patient undergoes radiation. Follow-up CT scans after irradiation are needed only to determine whether the mass seen on the staging scan has sufficiently diminished in size to become resectable. Benign bone defects can simulate metastatic foci, and nonopacified bowel loops can be mistaken for a tumor mass. Perforation of a colon cancer can result in an inflammatory mass or abscess, which makes diagnosis of the underlying cancer difficult (see Fig. 59-29).⁸⁹ Cachexia can lead to loss of fat planes, which mimics direct invasion of tumor into surrounding structures.

Preoperative Staging by Computed Tomography

The staging of colon tumors has usually been based on Dukes' classification⁹⁰ or a modification (Table 59-1).^{91,92} CT staging is based on an analysis of the thickness of the colon wall, extension beyond bowel wall margins, and presence or absence of tumor spread to lymph nodes and adjacent and distant organs.⁹³ The size of a primary or recurrent colon tumor can be measured and the tumor assigned to one of four stages, depending on the CT findings (Table 59-2).

Many surgeons use the tumor, node, metastases (TNM) classification (see Table 59-1) for staging colon neoplasms.⁹⁴ It has the advantage of more precise definition of the depth of infiltration in the bowel wall. Because of the inability of CT to

Figure 59-28 Rectal tumor with direct extension to the mesorectal fascia and locoregional lymphadenopathy (T3N1M0 or Dukes' stage C2). **A.** Large rectal mass with broad-based extension of soft tissue (arrows) into perirectal fat and direct invasion of mesorectal fascia (arrowheads). **B.** Several centimeters above the level of **A**, rectal wall is markedly thickened but tumor does not extend into piriform muscle (thick arrow) or bladder. Note enlarged perirectal lymph node (thin arrow).

Figure 59-29 Perforation of mucinous adenocarcinoma of the descending colon (T4N0M1). **A.** Nodular thickening of the descending colon (long arrows) is seen with stippled calcifications in the medial wall (short arrows) and a fluid collection with ill-defined rim representing the abscess (arrowheads). **B.** On this coronal reconstruction, the circumferential wall thickening (short arrows) with the perforation and large adjacent abscess (long arrows) is clearly demonstrated. Note also the ascites with enhancing peritoneum (arrowheads) representing peritonitis and the calcifications (black short arrows) within the metastases in the liver.

TABLE 59-1 Surgical-Pathologic Staging of Colorectal Neoplasm (Dukes' and TNM Classification)			
Astler-Coller Classification (Modified from Dukes')	TNM Staging	Description	Approximate 5-Year Survival (%)
A or I	T1N0M0	Nodes (–), limited to mucosa ± submucosa	80
B1 or I	T2N0M0	Nodes (–), limited to muscularis ± serosa	70
B2 or II	T3N0M0	Nodes (–), transmural into subserosa or into nonperitonealized perirectal or pericolic tissue	60-65
C1 or III	T2N1M0	Nodes (+), limited to muscularis ± serosa	35-45
C2 or III	T3N1M0	Nodes (+), transmural into subserosa or into nonperitonealized perirectal or pericolic tissue	25
	T4aN1M0	Nodes (+), perforation of tumor mass	
	T4bN1M0	Nodes (+), extension into adjacent organs or structures (e.g., muscle, nerve, bone)	
D or IV	Any T and N, M1	Any of the above, plus distant metastases	<25

determine depth of invasion to or through the various layers of the colon, CT findings cannot be correlated easily with the TNM classification. For example, tumor limited to mucosa or submucosa (T1N0M0) cannot be distinguished from tumor invading the muscularis or infiltrating to but not through the serosa, if present (T2N0M0). Generally, lesions extending beyond bowel wall (T3 and T4) are correctly identified by CT unless microinvasion by tumor is present. Assessment of regional lymph node (N) involvement and distant metastases (M) must be added to the evaluation of the depth of tumor invasion.

Early reports suggested that CT findings related to local extent and regional spread of tumor correlated well with surgical and histopathologic findings, and accuracy rates of 77% to 100% were reported.^{84,93,95-97} The high accuracy rates of these reports were largely because of the more advanced cases in these series. For primary colon cancer, CT is more accurate in showing extensive invasion of surrounding tissue and distant metastases than in demonstrating local adenopathy or minimal tumor extension.

CT frequently understages patients with microinvasion of pericolic or perirectal fat or small tumor foci in normal-sized nodes. Lymph node metastases were not analyzed separately in some of the earlier studies. In a meta-analysis that analyzed local staging and lymph node involvement in patients with

rectal cancers, summary estimates of sensitivity and specificity for CT in assessing perirectal tissue invasion and invasion of adjacent organs were 79% and 78% and 72% and 96%, respectively.⁴² In the same study, the summary estimates of sensitivity and specificity for CT in detecting lymph node involvement were much lower and reached only 55% and 74%, respectively.⁴² One study found that staging accuracy increased from 17% for Dukes' B lesions to 81% for Dukes' D lesions.⁹⁸ In another meta-analysis, the mean weighted sensitivity of helical CT for detecting hepatic metastases, mostly from colon carcinoma, was 72% at a specificity of higher than 85%.⁹⁹ Some individual studies have reached higher sensitivities for hepatic metastases from colorectal carcinoma.⁴¹

The accuracy of CT assessment of local tumor extent can be improved by prior colonic cleansing, prone positioning of the patient, air distention of the rectum, or administration of water enemas to serve as a low-density intraluminal contrast agent.^{100,101} Also, lowering the size threshold for diagnosing lymph node metastases improves the sensitivity for detecting such deposits, but this approach decreases specificity.

Little information is available about the CT detection and staging of tumors in the cecum or ascending, transverse, and descending colon. Most tumors in these areas are easily demonstrated (Figs. 59-30 and 59-31), but no investigation has analyzed these lesions in detail.

TABLE 59-2 Computed Tomography Staging of Primary or Recurrent Colorectal Tumor with TNM Correlation

CT Stage	TNM Staging	Description
I	T1	Intraluminal mass without thickening of wall
II*	T2	Thickened large bowel wall (>0.6 cm) or pelvic mass, no extension beyond bowel wall
IIIa*	T3	Thickened large bowel wall or pelvic mass with invasion of adjacent pericolic or perirectal tissue but not to mesorectal fascia
IIIb*	T3	Thickened large bowel wall or pelvic mass with invasion of adjacent pericolic or perirectal tissue with extension to mesorectal fascia
IIIc*	T4a and b	Thickened large bowel wall or pelvic mass with perforation or invasion of adjacent organs or structures, with or without extension to pelvic or abdominal walls but without distant metastases
IV*	Any T, M1	Distant metastases with or without local abnormality

*With or without lymphadenopathy (N0 or N1).

Modified from Thoeni RF, Moss AA, Schnyder P, et al: Detection and staging of primary rectal and rectosigmoid cancer by computed tomography. *Radiology* 141:135-138, 1981.

Figure 59-30 Near-complete colonic obstruction caused by tumor near splenic flexure (T3N1M0 or Dukes' stage C1). **A.** Axial MDCT scan demonstrates positive rectal contrast (thick arrows) in descending colon near the splenic flexure but no rectal contrast entering the fluid-filled and distended transverse and ascending colon (thin arrows). **B.** Two centimeters above level of **A**, obstructing tumor is demonstrated and its proximal border well outlined by retained colonic fluid (arrows). Tumor was underestimated by MDCT to be stage T2. Note subcentimeter lymph nodes (arrowheads) near the tumor in mesentery. They were confirmed to be positive for tumor at surgery but not prospectively diagnosed because of their small size.

Further studies are needed to establish whether new-generation CT scanners, especially MDCT with 16- or 64-slice capability, can compete with MRI in staging colorectal tumors. One study has already demonstrated that reformats could significantly increase the accuracy of T staging of rectal tumors

Figure 59-31 Cecal adenocarcinoma (T3N1M0). The cecum demonstrates eccentric wall thickening (*short arrows*) near the ileocecal valve, with nodular outer margins and soft tissue strands (*arrowheads*) extending into pericolic fat, suggestive of infiltration beyond the bowel wall. Abnormal local lymph nodes (*long thin arrows*) are present and were confirmed as pathologic at surgery.

Figure 59-32 MRI scans of adenocarcinoma of the rectum (T3N1M1; Duke's stage D).

A. Axial T2-weighted fast spin-echo image scanned perpendicular to long axis of tumor demonstrates eccentric thickening of anterior rectal wall (*thick arrow*), with extension of tumor to rectal sidewalls. Perirectal lymph nodes (*arrowheads*) are identified. The middle rectal vessels (*thin arrows*) in the lateral ligament are seen lateral to mesorectal fascia (*large arrowheads*). **B.** On this axial T1-weighted spin-echo MR image, the mesorectal fascia (*arrowheads*) is not as clearly delineated as on the T2-weighted image. **C.** Axial T1-weighted fat-suppressed image after administration of gadolinium shows enhancement of mesorectal vessels (*thin arrows*) bilaterally. Extension of tumor into the perirectal fat (*large arrows*) is best seen on this fat-suppressed sequence; however, a desmoplastic reaction alone cannot be definitively distinguished in this case from desmoplastic reaction containing tumor cells. **D.** Axial T2-weighted image with fat suppression identifies multiple liver metastases (*arrows*).

(see Figs. 59-18 and 59-22).⁶⁹ In this study, the staging accuracy based on axial slices ranged from 77% to 81%, whereas it increased to 90% to 98% when axial slices were combined with multiplanar reformats.⁶⁹ These results compare favorably with CT studies from the last decade that did not use MDCT, with accuracy rates ranging from 41% to 82%.^{26,102,103} MDCT offers the advantages of combining local, regional, and distant staging in one study, ultrathin slice capability, very fast imaging times, reconstruction in any desired plane, and lower cost compared with MRI.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging can be used to detect and stage rectosigmoid tumors more accurately than tumors in other areas of the colon. As with CT, this increased accuracy is because of the fixed position of the rectosigmoid colon in relation to the pelvis. Therefore, most reports have focused on the depiction and staging of rectal tumors. For accurate depiction of the intraluminal component of rectal tumors, particularly smaller ones, it may be necessary to prepare the colon to avoid confusion with feces. Rectal air insufflation, with prone positioning of the patient and an antispasmodic agent, may be helpful in depicting the tumor better. Other investigators have recommended axial T2-weighted imaging perpendicular to the long axis of the tumor, as seen on sagittal views, for more accurate staging (Fig. 59-32).¹⁰⁴ On T1-weighted spin-echo images, rectosigmoid tumors produce wall thickening with signal intensity similar to or slightly higher than that of skeletal muscle (long T1; see Fig. 59-32A). Because perirectal fat has

high signal intensity (short T1), air has no signal intensity, and tumor has moderate signal intensity (long T1), tumors are shown with high contrast. For the same reason, extension of tumor beyond the colon wall may be seen on T1-weighted images (Fig. 59-33). On T2-weighted spin-echo images, the signal intensity of tumor increases relative to that of muscle (see Fig. 59-33A) and the neoplasm in the rectal wall may be well visualized on high-resolution MRI.

Whereas early studies indicated that T2-weighted images are not as useful as T1-weighted images for determining extracolonic tumor extension (see Fig. 59-32),¹⁰⁵ it is now generally accepted that T2-weighted sequences are superior to T1-weighted scans in evaluating the extent of tumor in relation to the rectal wall layers and mesorectal fascia.^{106,107} Several studies have shown that T2-weighted sequences can demonstrate the mesorectal fascia, which has gained importance since the introduction of total mesorectal excision (TME).¹⁰⁶⁻¹¹⁰

In TME, the entire mesorectal compartment is removed, which consists of the rectum, surrounding mesorectal fat with the perirectal lymph nodes, and a thin fascia that envelops the two former structures; it is known as the mesorectal fascia. The TME procedure reduces the chance that tumor is left behind.

Even without preoperative or postoperative radiation therapy, the recurrence rate after TME is reported to be less than 10%.¹¹¹ If uterine or pelvic sidewall invasion is suspected, T2-weighted sequences also are useful because of the differences in signal intensity among muscle, fat, tumor, and muscle invaded by tumor.

Today, MRI using thin sections and phased-array coils can distinguish between tumors localized to mucosa and submucosa (stage I or T1) and those that infiltrate the entire colonic wall (stage II or T2), with a moderate to good staging accuracy (65%-86%; Table 59-3).¹¹⁰ The detection of the tumor in the bowel wall based on T2-weighted imaging relies on signal intensity differences between the intermediate signal intensity of the tumor, low signal intensity of normal mucosa and muscularis propria, and high signal intensity of the submucosa and perirectal or pericolic fat. Endoluminal MRI coils also make visualization of the layers of the rectal wall feasible and have demonstrated improved accuracy for T staging when compared with phased-array external coils (accuracy ranging from 71%-91%).¹¹² Endoluminal MRI is not widely available and, because of its small field of view, it cannot visualize the mesorectal fascia and surrounding pelvic structures.

Figure 59-33 MRI scans of rectal adenocarcinoma with extension beyond the bowel wall (T3N1M0; Dukes' stage C2). **A.** Axial T2-weighted fast spin-echo image demonstrates a nodular outer margin of the posterolateral rectal wall with broad-based extension of soft tissue (small arrows) into perirectal fat. The luminal margin of the tumor is irregular (arrowheads), and signal intensity of the tumor is higher than that of the muscularis propria (large arrow). **B.** Axial T2-weighted fast spin-echo image shows spiculated outer margin (arrows) of mass involving posterior and right lateral aspects of the rectum. These features suggest a desmoplastic reaction related to tumor rather than neoplastic infiltration of perirectal fat. **C.** Axial T2-weighted fast spin-echo scan at higher level than **A** and **B** depicts prominent presacral lymph nodes (arrows) indicative of malignant lymphadenopathy slightly remote from primary tumor (N2). **D.** Sagittal T2-weighted fast spin-echo image confirms enlarged lymph nodes (large arrows) in the presacral space. The nodular outer margin of the rectal mass (thin arrows) is well demonstrated on sagittal view, suggesting invasive tumor (T3).

TABLE 59-3 Criteria for Magnetic Resonance Imaging Staging of Rectal Cancer

Tumor (T) Stage	MRI Criteria
T1	Tumor signal intensity confined to mucosal and submucosal layer; signal intensity low compared with high signal intensity of the adjacent submucosa
T2	Tumor signal intensity extends into muscle layer, with loss of interface between submucosa and circular muscle layer
T3	Tumor signal intensity extends through muscle layer into perirectal fat, with obliteration of interface between muscle and perirectal fat
T4	Tumor signal intensity extends into adjacent structure(s) or viscus

Modified from Brown G, Richards CJ, Newcombe RG, et al: Rectal carcinoma: Thin-section MR imaging for staging in 28 patients. *Radiology* 211:215–222, 1999.

Microinvasion into surrounding fat cannot be detected by MRI, which leads to understaging, whereas peritumoral tissue inflammation and fibrosis can lead to overstaging.¹¹³ However, if the feature of a nodular or pushing configuration of an advancing tumor margin is used, tumor extension beyond the bowel wall can be distinguished in most cases from the spiculated and low signal intensity of peritumoral fibrosis.¹⁰⁴ Because the mesorectal fascia can be readily recognized on MRI and the depth of transmural tumor invasion (T3) can usually be diagnosed accurately, MRI is more sensitive and reliable for predicting the circumferential resection margin (CRM) than overall T stage of tumor (Fig. 59-34).¹¹⁴ For the surgeon, it is important to obtain information on the distance between the rectal tumor and mesorectal fascia. A pathologically involved margin in rectal cancer is defined as tumor within 1 mm of the surgical CRM.¹¹⁵

Tumor foci in normal-sized nodes may go unrecognized.¹¹⁶ If the MRI diagnosis of lymph node abnormality is based on mixed signal intensity and irregular outer margins, rather than size of the nodes, the MRI prediction of nodal involvement can be improved.¹¹⁷ In one older series, in five of six cases in which

Figure 59-34 MRI scans of rectal adenocarcinoma with extension to mesorectal fascia (T3N2M0) before and after neoadjuvant chemotherapy and radiation). **A.** This T2-weighted MRI scan demonstrates rectal wall thickening with the tumor extending posteriorly beyond the rectal wall (long arrows) and reaching the mesorectal fascia (short arrows), which is well shown in this view. **B.** Following treatment, the rectal wall is less defined on this high-resolution MRI scan and shows multiple thin spicules (short arrows) extending from the rectal wall into the perirectal fat. This represents acute radiation change and not tumor extension. Posteriorly, the tumor extension to the mesorectal fascia (long arrows) is still present but slightly reduced compared to image **A**. **C.** Axial T2-weighted MRI scan demonstrates an enlarged round perirectal node (red arrow). **D.** Following neoadjuvant chemotherapy and radiation, an axial T2-weighted MRI scan close to the same level as **C** shows the same node (red arrow), which now is considerably smaller. Note the edema in the rectal wall (long arrows) above the tumor following radiation.

lymph nodes were seen, the nodes were normal in size but contained tumor and, in the one case with enlarged nodes (>15 mm in diameter), reactive hyperplasia was present.¹⁰⁷ In a more recent series with nodes considered suspicious based on irregular borders and mixed signal intensity, 51 of 60 were correctly identified as malignant (sensitivity, 85%) and 216 of 221 were considered nonmalignant (specificity, 97%).¹¹⁷

For demonstration of liver and adrenal metastases, MRI and CT are comparable if an optimal CT bolus technique is used.⁹⁹ MRI with a liver-specific contrast agent such as mangafodipir (Teslascan, Nycomed, Princeton, NJ) or iron oxide particles (Feridex, Berlex, Wayne, NJ) may render MRI superior to CT, particularly for the detection of small lesions.^{118,119} However, these liver-specific agents have not found wide acceptance, and Teslascan is no longer available. Generally, most MRI for colorectal tumor staging and suspected liver metastases still is performed after administration of gadolinium, and excellent results have been achieved with a newer liver-specific contrast agent, gadoxetate disodium (see earlier).¹²⁰

Invasion of adjacent organs is best demonstrated with transverse or coronal high-resolution MRI. MRI is superior to CT in demonstrating invasion of the levator ani (Fig. 59-35), puborectalis, or internal and external sphincter muscles. Lateral extension of tumor is difficult to detect on sagittal MRI scans but can be assessed accurately with axial images.¹¹⁴ Extension into the prostate, seminal vesicles, vagina, and cervix can be shown well by MRI, but extension into the bladder may be missed if the bladder is not well distended.

Preoperative Staging by Magnetic Resonance Imaging

The introduction of neoadjuvant preoperative radiation and/or chemotherapy and TME has made accurate preoperative staging even more critical in patient management and identifying those at risk for local recurrence. The risk of local recurrence ranges from 3% to 32%, and patients with positive resection margins are much more likely to suffer from local tumor recurrence.¹¹⁴ Based on the different risk categories, the treatment is tailored to the individual patient. In the United States, patients with

fixed T3 tumors and/or positive local nodes routinely undergo postoperative radiation and chemotherapy, but preoperative radiation is reserved for those with tumor extension to the pelvic sidewalls. In Europe, large trials have shown that the recurrence rate is markedly reduced if patients receive preoperative radiation, and therefore it is routinely performed in all patients with rectal cancer.¹²¹ Imaging should provide the following staging information: depth of tumor growth in the rectal wall, circumferential resection margin at the time of TME, degree of tumor invasion into surrounding pelvic structures, and nodal status. Edema, granulation tissue, and fibrosis can lead to overstaging in patients who undergo MRI after neoadjuvant chemotherapy and irradiation (Fig. 59-36).

Endoluminal MR and endoluminal ultrasound (see later) are the two most accurate methods for staging early or superficial rectal cancer that can be treated with surgery alone. Accuracies ranging between 71% to 91% for MRI and 70% to 94% for TRUS have been reported.^{114,122-125} These two methods are considered superior to CT in staging early tumors. However, both techniques have a limited field of view, and neither method can adequately assess the mesorectal fascia and CRM.

At present, for advanced mobile or fixed rectal cancers, MRI with phased-array coils and high spatial resolution (thin sections) generally appears to be better suited for demonstrating the mesorectal fascia and CRM than CT (see Fig. 59-32).¹¹⁴ In a meta-analysis, the sensitivity of MRI for invasion of the muscularis propria was 94%, similar to that of TRUS, but the specificity was significantly lower for MRI (69%) compared with TRUS (86%).⁴² In the same meta-analysis, at comparable specificities, the sensitivity of MRI for perirectal invasion was 82% compared with 79% for CT and 90% for endoluminal ultrasound, whereas the sensitivity of MRI for adjacent organ invasion was 74%, similar to the 72% for CT and 70% for endoluminal ultrasound.⁴² Overall, it appears that MRI may currently be slightly superior to CT in assessing extension of tumor into surrounding pelvic structures, especially for demonstrating direct invasion of tumor into pelvic sidewalls, sciatic nerves, or subtle invasion of bone marrow.¹²⁶ In one study of patients with known peritoneal carcinomatosis, it was shown that MRI had a higher sensitivity (84%) than CT (54%) for detecting peritoneal carcinomatosis if fat-suppressed

Figure 59-35 MRI scans of rectal adenocarcinoma with extension into the levator ani muscles (T3N0M0; Dukes' stage B2). **A.** Axial T1-weighted spin-echo image after gadolinium demonstrates thickening and enhancement in posterior and right lateral rectal wall administration, with direct invasion of tumor into levator ani. This suggested extension by increased signal intensity of muscle in invaded area (arrow). Compare this appearance to the normal left levator ani, which has low signal intensity (arrowhead). **B.** Tumor invasion into the levator ani is difficult to diagnose on T1-weighted sequence without gadolinium.

Figure 59-36 MRI scans of rectal adenocarcinoma with extension into the perirectal fat (T3N0M0; Duke's stage B2) in a patient who underwent neoadjuvant chemotherapy and radiation therapy. **A.** Axial T2-weighted spin-echo image shows a lobular wall thickening in anterior rectal wall (arrow) and mild thickening of remainder of rectal wall. Outer rectal wall margins are ill defined because of radiation therapy. Mixed signal intensity of perirectal fat with blurring of outer rectal wall and high signal intensity in presacral space are most likely secondary to post-treatment granulation tissue and retroperitoneal fluid. This makes accurate staging of this tumor more difficult. **B.** T1-weighted image does not suffer from as many postradiation artifacts, as does a T2-weighted sequence. Arrowheads, presacral fluid collection.

T2-weighted and gadolinium-enhanced T1-weighted sequences with breath holding were used.¹²⁷ However, a more recent study concluded that the use of gadolinium enhancement did not improve the diagnostic accuracy of MR for assessing tumor penetration through rectal wall and tumor extension into mesorectal fascia.¹²⁸ Diffusion-weighted imaging can be useful for identifying lymph nodes and, at times, the primary rectal cancer when the tumor is difficult to visualize with other sequences.¹¹⁶

Because the radiologic detection of nodal tumor involvement relies on morphologic criteria such as size, contour margins and signal intensity, it is difficult to distinguish between reactive and metastatic nodes. Also, micrometastases can easily be missed. Rectal tumors tend to produce micrometastases¹²⁹ but, in the perirectal fat, any node can be considered malignant because reactive lymph nodes are rare in this area. Because cross-sectional imaging uses morphology to diagnose metastases to lymph nodes, reliable detection of lymphadenopathy is not possible at present. The accuracy rates for unenhanced MRI for detection of nodal involvement range from 39% to 95%.^{105,114,123} Large variations in the accuracy for detecting nodal metastases also have been published for CT (22%-73%) and TRUS (62%-83%).^{114,130} Some promising results have been reported on the use of ultrasmall superparamagnetic iron oxide particles that are phagocytosed by the reticuloendothelial system and cause shortening of the T2* relaxation time and subsequent decrease of the signal intensity of normal lymph nodes, but not in nodes with metastatic deposits.¹³¹ Uniform and central low signal intensity patterns are suggestive of nonmalignant nodes, whereas eccentric or uniform high signal intensity patterns suggest malignant nodes.¹³² Its use for colorectal cancer needs further investigation.

Overall, for the definitive analysis of these staging results, a comparison between state of the art MDCT and MRI in large clinical trials is needed. At present, most comparative studies

have used state of the art MRI but not the latest imaging technology with CT. The advantages of MDCT with ultrathin sections and very short imaging times, particularly with 64-slice scanners, optimized bolus techniques, and multiplanar reformats have not been fully explored. Although one study indicated that improved staging accuracy could be achieved with the inclusion of multiplanar reformats,⁶⁹ no direct comparison to MRI or TRUS is currently available in larger prospective series.

TRANSRECTAL ULTRASOUND

Primary Tumor

The major advantage of endoluminal ultrasound or TRUS is that it can depict the various layers of the colon wall, which enables determination of the depth of mural tumor penetration. Colorectal tumors present as a hypoechoic mass whose margins can be outlined and related to the layers in the colon or rectal wall. The depth of infiltration can be assessed from evidence of disruption of the different segments of the rectal or colon wall. On images produced with a radial rotating transducer placed in the rectum, the elements of the rectal wall appear as rings of different echogenicities. The transducer is covered with a balloon filled with water. The innermost ring is hyperechoic and represents the interface of the balloon and mucosa. The second ring from the center is hypoechoic and is produced by the muscularis mucosae. The third ring is hyperechoic and consists of the submucosa. The fourth ring is hypoechoic and is formed by the muscularis propria. The fifth ring is hyperechoic and is caused by the perirectal fat or, if it is in an area with peritoneal reflection, by the serosa and fat.

If the examination is performed carefully, even the intraluminal component of the tumor can be clearly demonstrated as a polypoid or exophytic mass. Filling of the balloon attached to the transducer and colorectal lumen with water allows optimal

visualization of mural and nodal abnormalities. In one study, the accuracy of TRUS for local tumor staging was 85% with intrarectal administration of water and only 57% without water administration.¹³³ Pericolonic or perirectal abnormalities can also be seen, but depth of penetration beyond the colon or rectal wall is limited. Whenever possible, the transducer is passed beyond the tumor into the colon proximal to the lesion for more complete assessment of mural and nodal pathology. Peritumoral inflammation and irradiation may simulate more advanced tumor changes because these abnormalities often have a hypoechoic pattern that may be indistinguishable from the echo pattern of tumor. This leads to overestimation of the size of the neoplasm. Tumors that severely narrow the lumen may not be completely assessed by endoluminal ultrasound because it may not be possible to pass the probe through the area of stenosis. Also, high location of the tumor may prevent its evaluation by TRUS.

The ultrasonographic staging system is based on the TNM classification.¹³⁴ Three stages are distinguished by ultrasonography. A T1 tumor is confined to the mucosa and submucosa, with the echogenic layer of the submucosa thinned and irregular. It does not interrupt the middle echogenic interface to the muscularis propria. A T2 lesion is confined to the rectal wall and involves the hypoechoic muscularis propria. The outermost echogenic interface is intact. T3 tumor penetrates into the perirectal fat and is visualized as a disruption of the outermost hyperechoic ring (Fig. 59-37). Stage T4 may be assessed by endoluminal ultrasound but it is often beyond the limited field of view because T4 represents extension into adjacent organs or pelvic sidewall structures.

On TRUS, normal lymph nodes are hyperechoic and bean-shaped and have indistinct margins. Consequently, they are not routinely seen within the echogenic perirectal fat. Tumors containing lymph nodes are spherical hypoechoic structures with distinct margins. According to the TNM classification, stage N1 is present when TRUS visualizes one to three hypoechoic nodes and stage N2 is present if TRUS sees four or more of these hypoechoic lymph nodes.

Smaller probes that can be introduced through the biopsy channel of an endoscope and pass through a severe luminal stenosis allow more accurate staging because the complete tumor extent can be visualized. The echo-endoscope has become the instrument of choice for visualizing proximal colon

neoplasms because the transducer can be maneuvered into the proximal segments of the colon. In one diagnostic and staging procedure, the combination of endoscope and TRUS can serve the following functions: demonstrate the surface of the mucosa, obtain a biopsy specimen, visualize the depth of a lesion within the bowel wall, and determine the presence or absence of adjacent lymphadenopathy.^{135,136} However, CT or MRI is needed for complete staging, especially for detecting distant metastases.

Preoperative Staging by Endoluminal Ultrasound

Although transabdominal sonography may be used to assess the presence or absence of liver metastases, TRUS is increasingly used to detect the depth of tumor infiltration and local adenopathy in patients with rectal carcinomas. As noted, its ability to distinguish the normal layers of the bowel wall and visualize disruption of one or more of these layers by tumor leads to accurate staging of local tumor extent. With this method, sensitivities of 67% to 96% have been reported for assessing perirectal spread but the presence of regional lymph node metastases is less well detected (sensitivity, 50% to 70%).^{42,134,137-140} One study has shown that results were less accurate with T2 carcinomas, which were often accompanied by peritumoral inflammation or abscess.¹⁴¹ Abscesses manifest as fluid-filled structures, usually in the perianal space, that may contain internal echoes but exhibit good posterior acoustic enhancement. In their study of transcolorectal endosonography, the authors achieved an accuracy of 81% for rectal and 93% for colon carcinomas, with overstaging in 13% and understaging in 2% of patients. When lymph node involvement was analyzed separately, the sensitivity was 94% and specificity 55% for an overall accuracy of 70%. When transcolorectal ultrasound was compared with Dukes' classification, the overall accuracy was 67%.

The broad range of sensitivities of TRUS for the detection of tumor extent in and through the bowel wall emphasizes the operator dependence of this method. This fact was well demonstrated in a multicenter trial in which experienced ultrasonographers with a large caseload of patients with rectal cancers achieved the highest accuracy with TRUS.¹⁴² TRUS has expanded the application of ultrasonographic methods to the entire colon, and even ultrasound-guided biopsies of submucosal and extrinsic masses of the colon and rectum have become possible with this technique.^{135,143,144} Spontaneous or iatrogenic inflammation is a major limiting factor affecting diagnostic

Figure 59-37 Transrectal ultrasound of rectal tumor (T3N1). **A.** TRUS image shows several lymph nodes in perirectal fat (arrows) and marked thickening (arrowhead) of rectal wall. **B.** TRUS image demonstrates thickened anterolateral wall of rectum as a low echogenicity structure with nodular outer margin (arrows) against the surrounding high signal intensity fat. This indicates transmurum tumor extension (T3).

accuracy.¹⁴⁵ Transrectal volume scans obtained using a 3D multiplane transducer (7.5 to 10.0 MHz) permits examination of rectal cancer using previously unattainable planes and 3D views¹⁴⁶ and may help improve tumor staging and treatment planning.¹⁴⁷ Because of the limited penetration of the ultrasound probe, only locoregional staging is possible with TRUS, and CT or MR need to be added for complete tumor staging.

IMMUNOSCINTIGRAPHY WITH MONOCLONAL ANTIBODIES

Detection of Primary Colorectal Neoplasm

Since the mid-1970s, MoAbs have been used in vivo as tumor-localizing agents and in vitro as diagnostic markers with gamma camera imaging to differentiate tumor cell types.^{44,148} Agents used include anticarcinoembryonic antigen (anti-CEA) MoAbs tagged with ¹²³I and ¹²⁵I, anti-CEA MoAbs conjugated with diethylenetriaminepentaacetic acid (DTPA) and labeled with ¹¹¹In, MoAbs B72.3-GYK-DTPA, designated as CYT-103 (¹¹¹In-labeled satumomab pendetide; MoAb B72.3-glycyl-tyrosyl-[N-e-DTPA] lysine), sodium iodide ¹²⁵I-labeled anti-TAG monoclonal antibody CC49, and MoAb ior c5.¹⁴⁹⁻¹⁵¹ The level of serum CEA did not influence tumor detection. MoAb B72.3 targets the high-molecular-weight tumor-associated glycoprotein 72, which is expressed in 80% of colon cancers and reacts with various mucin-producing adenocarcinomas, but has almost no reaction to normal tissues. Some patients require cathartic agents before imaging because of prominent radioactivity in the large bowel. In general, lesion detection is performed with planar imaging 3 to 4 days after MoAb infusion. Single photon emission CT (SPECT) is usually performed 5 to 7 days after MoAb infusion, and its better anatomic definition and determination of approximate size result in improved tumor detection.¹⁵² Most studies attempt to determine the maximum tolerated dose and uptake and retention of isotope in the tumor.¹⁵³

Primary adenocarcinomas of the colon and metastatic foci in liver or lymph nodes are seen as areas of increased radioactivity (hot spots). Depending on the size and degree of necrosis of the liver metastases, neoplastic deposits in the liver may be visualized as areas of intense accumulation of radioactivity, areas with no accumulation of radioactivity surrounded by normal liver uptake, and intermediate lesions, with uptake identical to that of normal liver. In one study using ¹¹¹In-labeled CYT-103, cold defects in the liver shown by immunoscintigraphy were found to represent areas with moderate to severe necrosis, whereas lesions with normal MoAb uptake had only minor degrees of necrosis.¹⁵² The same study revealed a low incidence of human antimouse antibody formation (16%) and an even lower incidence of adverse reactions (3.5%).¹⁵² Radioimmunoguided surgery (RIGS) with the monoclonal antibody CC49 labeled with ¹²⁵I has been used in the treatment of colorectal cancer and appears promising.^{150,154,155}

Preoperative Staging of Primary Colorectal Neoplasm

A number of studies have evaluated the value of isotope-labeled MoAb immunoscintigraphy for the detection of primary colorectal carcinoma and its metastases.¹⁴⁸⁻¹⁶² Sensitivity ranged from 65% to 95% and specificity ranged from 77% to 100% for the detection of primary tumor, local recurrences, and distant

metastases. The major role of immunoscintigraphy is detecting occult tumor lesions and establishing absence of distant disease in patients with isolated, resectable metastases. In one study¹⁶² using ¹¹¹In-labeled CYT-103, extrahepatic lesions undetected by CT and other tests were confirmed by surgery in more than 10% of patients. In another study, RIGS had a sensitivity of 92% and specificity of 88% for the detection of lymph node metastases.¹⁶² Also, immunoscintigraphy contributed beneficially to the management of 27% of patients.¹⁶⁰ It therefore appears reasonable to use immunoscintigraphy in patients with suspected focal or metastatic colorectal neoplasms. However, the validity of this test and low incidence of adverse reactions must be confirmed in larger series before a final conclusion can be drawn.

POSITRON EMISSION TOMOGRAPHY

Primary Colorectal Neoplasm

PET was initially used for the detection of functional abnormalities of the brain and heart, but its use has been expanded to the detection of primary and recurrent tumors as well as metastases. For these tumor studies, ¹⁸F-fluorodeoxyglucose (FDG) has been used, and a remarkable correlation has been found between tumor grade and the degree of glucose uptake.¹⁶³ The new generation of PET scanners has good resolution and can provide high-quality images of any area of the human body; it is possible to use this method to detect distant, residual, or recurrent disease in patients with colorectal carcinomas. With the introduction of the PET/CT system, lesion classification has been significantly improved.¹⁶⁴ Large series in patients with colorectal cancer are still needed to define the role of PET/CT more clearly in staging and treating these patients.

For the purpose of identifying tumor tissue, PET images are evaluated quantitatively in regions of interest and time-activity curves are calculated. Tracer uptake is expressed as a differential absorption ratio calculated as the tissue concentration (in mCi/g) divided by injected dose (mCi) per body weight (g). After IV injection of FDG, PET images show significant uptake by malignant tumors (Fig. 59-38). Quantitative analyses demonstrate rapid uptake of FDG by the tumor, followed by a slight decrease in the differential absorption ratio for up to 40 minutes after FDG administration. In comparison, the FDG concentration is low in nonmalignant lesions and in soft tissue. In general, 1 hour after tracer injection, FDG accumulation in tumors is more than twice as high as in normal tissue or nonmalignant lesions. Tumor imaging is best performed at that time. Colon cleansing and drainage of the bladder with a Foley catheter after administration of the isotope can minimize artifactual accumulation of FDG.¹⁶⁵

Staging of Primary Colorectal Neoplasm

The Centers for Medicare and Medicaid Services (CMS) first approved PET for coverage in 1998 and its guidelines specifically approve the use of FDG-PET for the diagnosis, staging, and restaging of colorectal cancer, but in clinical practice it is rarely used for the diagnosis of primary colorectal cancer unless the diagnosis has not been made pathologically.¹⁶⁶ Most investigations of the applications of FDG-PET for colorectal tumors have focused on the detection of local recurrent or residual disease. PET has also been used to identify distant metastatic foci and occasionally unexpected primary malignant tumors in patients with other colorectal neoplasms.^{47,163,167-173} Most studies

Figure 59-38 PET for staging in patient with history of splenic flexure carcinoma. **A.** Axial FDG-PET image demonstrates increased FDG uptake in anticipated location of splenic flexure (*large arrow*) and in liver (*small arrow*). Two additional areas of increased FDG uptake (*arrowheads*) are seen in expected location of hepatic flexure. **B.** The fused PET/CT scan shows that left flank activity is located in the splenic flexure primary tumor (*large arrow*), and a large area of increased activity on the right corresponds to hepatic lesion (*small arrow*) seen on CT. Two small areas of increased activity (*arrowheads*) were not seen on CT and represent small implants on surface of hepatic flexure. Although CT detected both primary tumor in splenic flexure and hepatic metastasis, serosal colonic implants were missed.

that addressed the sensitivity for identifying primary tumor by PET were retrospective and hampered by physiologic bowel wall accumulation of the isotope. This prevents the use of FDG-PET as an initial diagnostic modality.

Only small series are available, so the accuracy of PET with FDG for staging colorectal tumors remains to be determined. Even smaller numbers are reported for the PET/CT scanner. Nevertheless, the results with PET/CT are promising because of the superior localization of lesions. In one study of asymptomatic patients with colonoscopic correlation, PET/CT detected 13 villous adenomas and 3 adenocarcinomas and had 5 false-positive results.¹⁷² In this study, the authors were able to distinguish adenoma from carcinoma by an increased rate of glycolysis in carcinoma. Metastases have been shown in lymph nodes remote from the primary tumor site and in liver. The results for lymph nodes are not as promising as those for liver metastases. One study showed a sensitivity for regional lymph nodes of only 29% but a specificity of 96%.¹⁶⁸ These disappointing results are probably because many metastatic deposits from colon carcinoma to nodes are in close proximity to the primary tumor, are small, and are often not cell-rich, especially if the tumor is mucinous.

PET is excellent for the depiction of distant nodal or extra-nodal metastases. In one study, the positive predictive value of PET for malignant liver lesions was 93% and was superior to the 78% of CT or MRI.¹⁷⁴ PET is more accurate than CT for depicting hepatic metastases from colon carcinoma larger than 1 cm in diameter but frequently misses lesions smaller than 1 cm.¹⁷⁵ Because PET does not provide accurate information about the location of hepatic metastases according to hepatic anatomy, its best role lies in the detection of extrahepatic disease that precludes resection for cure (see Fig. 59-37). It appears that the addition of PET to the presurgical evaluation of patient with colorectal carcinoma may improve survival by eliminating patients with inoperable disease from consideration for surgical resection of liver lesions.¹⁷⁵ However, in a more recent study, PET/CT changed the treatment of patients with colorectal carcinoma in only 3.2% and the authors recommended against the routine use of PET/CT for primary staging of these tumors.¹⁷⁶

Cross-Sectional Imaging in Primary Colorectal Neoplasm Detection

CTC has been introduced as a method for screening patients at risk for colon cancer and polyps. The introduction of 2D and 3D CTC as complementary techniques has several advantages, including good patient tolerance, excellent visualization of abnormalities within the colon, and accurate detection of pathology proximal to an obstructing lesion (Fig. 59-38).^{177,178} Furthermore, 3D reconstruction with fly-through capability offers the advantage of complete antegrade and retrograde inspection of the entire colon, whereas retroflexion with the endoscope during colonoscopy cannot be achieved for all areas of the large bowel. Various technical approaches are still being explored to facilitate the process of evaluating the colon with CTC and further improve its sensitivity. CTC is discussed in detail in Chapter 53.

Patient prognosis in colorectal cancer is closely related to tumor stage at the time of diagnosis. The overall 5-year survival rate is about 61% (stage A, 81%-85%; stage B, 64%-78%; stage C, 27%-33%; stage D, up to 20%).^{175,179-181} There is consensus that the most important prognostic factor is the presence or absence of lymph node invasion, but malignant fixation of colorectal tumor through direct invasion also appears to be an important sign.¹⁸²

Most patients with colorectal cancer have disease that at the time of diagnosis is limited to the bowel wall and regional pericolic or mesenteric lymph nodes. These patients undergo curative surgery. In patients with advanced disease, surgery is performed to prevent hemorrhage, obstruction, and perforation. Both types of patients need accurate, noninvasive, preoperative assessment of tumor stage based on one or a combination of radiographic techniques to individualize the treatment plan. The rest of this section will analyze the effectiveness of various imaging techniques for detecting and staging primary colorectal neoplasms.

Endoluminal or endoscopic ultrasound is useful for determining local tumor extent within and beyond the bowel wall but may miss regional lymph node metastases, which develop in 14% of patients with primary tumors confined to the rectal

 Amyloidosis
 Focal chronic inflammation from pancreatitis
 Plication defects after surgery

wall. At present, endoluminal sonography is superior to CT and equal to MRI in demonstrating the T stage of tumors confined to the bowel wall (T1 and T2) and has a higher specificity.⁴² Endoluminal ultrasound appears to be more sensitive in assessing early perirectal invasion, but its sensitivity does not reach 100%.

Based on the available results, routine CT or MRI staging is not recommended for early primary colorectal tumors. Wall thickening alone is a nonspecific finding that occurs in many different diseases (Box 59-1). Endoluminal MRI can achieve results for T1 and T2 staging similar to endoluminal ultrasound, but this method is rather invasive and not widely used. Both endoluminal techniques are limited when a large obstructing colorectal mass is present. MRI with phased-array coils is capable of demonstrating the layers of the rectal wall.

Overall, CT and MRI should be reserved for patients with suspected locally invasive (T3 or T4) or metastatic disease. If CT or MRI shows extensive local tumor, these patients can be treated with neoadjuvant radiation therapy and chemotherapy with subsequent tumor resection. In the United States, chemotherapy and radiation therapy are reserved for patients with T3 disease, but in Europe all patients with rectal carcinoma receive preoperative irradiation, with or without chemotherapy. Neoadjuvant therapy has proven to reduce rectal tumor recurrence dramatically.¹²¹

If a colon resection is planned, the decision to use local tumor excision by surgery or colonoscopy cannot be based on CT alone. CT has poor sensitivity in depicting depth of mural tumor penetration and is less sensitive than other techniques for assessing invasion of the mesorectal fascia and regional lymph nodes. CT can be used to guide fine-needle aspiration of suspected metastases and assess complications, such as abscess formation. When the primary neoplasm arises in the abdomen, pelvic metastases are uncommon, and isolated pelvic metastases are rare, which focuses the metastatic work-up on the abdomen.^{183,184} Subtle extension of tumor beyond the bowel wall may be better recognized by MRI than by CT, whereas advanced T3 usually is diagnosed equally well by both techniques. In these cases, the choice of method is largely determined by the operator's skills and experience. At present, MRI is considered superior to CT in demonstrating the mesorectal fascia and determining the exact distance of the tumor from it.

Invasion of the muscles, nerves, and bones may be better delineated on MRI than on CT.¹²⁶ Because in-depth studies are not available that compare MDCT with 16 or 64 detector rows to state of the art MRI, a definitive assessment of the respective advantages of the two techniques cannot be made.

Large variations in sensitivity and specificity for detecting metastases in lymph nodes have been published for all three techniques. Endoluminal ultrasound has limited depth penetration and therefore can only be used for the detection of locoregional nodes. All techniques suffer from the fact that small metastatic deposits in lymph nodes may go undetected. MR lymphangiography may improve staging of colorectal tumors, but MR lymphangiography with target-specific contrast material is not yet commercially available.

The role of MoAb immunoscintigraphy and PET in the evaluation of patients with primary colorectal tumors is still uncertain. Results with immunoscintigraphy are encouraging, with sensitivities for detecting primary colorectal tumor ranging from 65% to 95% and specificity from 77% to 100%. Furthermore, RIGS was shown to guide resection of malignant lymph nodes successfully.¹⁶² Specifically, this test may lead to more accurate assessment of distant disease for resection. Similarly, PET has become an accurate method for staging colorectal neoplasms because the resolution of PET scanners has improved, and combined PET/CT provides more accurate lesion localization. Although the sensitivity of PET for detecting hepatic metastases larger than 1 cm in diameter is superior to that of CT or MRI, CT or MRI should be used initially for detecting liver metastases and localize them precisely to the various liver segments. MRI with a liver-specific contrast agent has the advantage of detecting liver metastases with a high sensitivity and can readily detect lesions smaller than 1 cm. The most important role of PET in the presurgical evaluation of patients with colorectal cancer is in the detection of extrahepatic disease that precludes resection for cure.

In conclusion, a combination of endoluminal ultrasound (or endoluminal MRI) for local and CT for overall staging is optimal for early colorectal cancer. Whether the addition of PET is beneficial and cost-effective in these patients remains to be seen. In suspected advanced disease, MRI appears to be superior to CT for local staging and assessing the presence or absence of liver metastases, and it should be combined with PET/CT for complete staging and preoperative treatment planning. Intraoperative ultrasound can be used to confirm the presence or absence of hepatic metastases.

Postoperative Follow-Up

CONTRAST ENEMA

Patients who have had surgery for colorectal carcinoma should undergo frequent postoperative examinations because of their relatively high risk for developing a recurrent and metachronous carcinoma.¹⁸⁵ Ileocolic (Fig. 59-39) and colocolic anastomoses are well depicted on double-contrast enema examination, particularly after the use of IV glucagon. Plication defects are frequently identified. In some patients, a filling defect resulting from a stitch granuloma may be seen in the early postoperative period (Fig. 59-40). This defect regresses and becomes less prominent on follow-up studies.¹⁸⁶ It is important to obtain a postoperative study within approximately 3 months of surgery to establish the baseline appearance of the

Figure 59-39 Normal postoperative appearances.

anastomosis for comparison with subsequent studies. The surgical anastomoses of low anterior resections performed with a surgical stapler are beautifully demonstrated by double-contrast technique (Fig. 59-41).¹⁸⁷ CT is the examination of choice for the detection of recurrence remote from the anastomotic line and detection of distant metastases (see later).^{188,189}

The double-contrast enema is the primary diagnostic procedure for the detection of local and anastomotic recurrences (Fig. 59-42), as well as metachronous lesions (Fig. 59-43). It is

particularly important to examine the anastomotic site because metastatic deposits tend to be implanted there.^{190,191} Welch and Donaldson have shown that 20% of recurrences after colon resection and anastomosis are found at the anastomotic site.¹⁹² When the anastomotic site appears eccentric or irregular or has nodular filling defects, recurrent tumor should be suspected. Colonoscopy may be helpful, although in some cases it may be misleading because recurrent tumor may be submucosal and biopsy findings may be negative for malignancy. CT and

Figure 59-43 Metachronous carcinoma. A colostomy enema study performed after total proctectomy for carcinoma shows new primary carcinoma (arrow) in the descending colon.

CT-guided biopsy may be needed to determine the presence and nature of an extracolonic mass, which cannot be appreciated to its full extent, if at all, by the barium enema.

Patients who have undergone abdominoperineal resection with colostomy must also be examined regularly because of the

possibility of developing a second tumor. Double-contrast examination of the residual colon can usually be performed through the colostomy (see Fig. 59-43 and Chapter 55). CT and MRI are of particular value for the detection of pelvic recurrence of tumor in patients who have undergone abdominoperineal resection.

CROSS-SECTIONAL IMAGING

CT and MRI have been used extensively to identify recurrent colorectal cancer, and both methods can detect recurrent tumor when CEA titers are normal and symptoms are absent.^{193,194} They are particularly useful in patients who have had total abdominoperineal resection. Follow-up studies of patients with potentially curative resection of recurrent tumor demonstrated an average symptom-free period of 38 months, compared with an average survival of 8 months for patients without resection of recurrent tumor.¹⁹⁵⁻¹⁹⁷ CT and MRI are accepted methods for detecting recurrent tumor that develops extraluminally. There is an ongoing debate on the appropriate timing and cost-effectiveness of these imaging tests. Rectal tumors have significantly more locoregional and pulmonary recurrences, whereas colon carcinomas have more hepatic and intra-abdominal recurrences.¹⁹⁷ Testing for asymptomatic recurrence during the first follow-up year is usually less fruitful than in the second through fourth follow-up years.^{185,198} Patients with local recurrence in the first year are less likely to have a successful second “curative resection.” Patients with low tumor grade at initial diagnosis are more likely to have a successful second surgical resection and a better prognosis.¹⁹⁹ Young patients with colon cancer have an increased prevalence of isolated local recurrences and a lower rate of liver metastases than older patients.²⁰⁰

The stage, histology, and site of primary tumor at the time of diagnosis have been found to be most predictive of eventual relapse.^{185,198,201} Anastomotic recurrence usually occurs after low anterior resection of a rectal tumor and is usually related to residual tumor outside the colorectal wall that grows into the suture site. Since the introduction of total mesorectal excision, the incidence of local relapse has been markedly reduced.²⁰² Pelvic tumor recurrence limited to the axial location or axial and anterior locations is more likely to be resectable than those involving the sidewalls.²⁰³ Because tumor recurrence develops in 30% to 50% of patients who have undergone apparently

Figure 59-44 Postoperative appearance of pelvis after rectal carcinoma resection and reanastomosis. **A.** Status postresection without recurrence. The staple line (arrowheads) is clearly identified. **B.** Recurrent rectal carcinoma with extension into perirectal fat (T3N0M0). Thickening of the rectal wall is seen on the left side (arrows). There is also extension into perirectal fat. Staples (arrowheads) outline the area of anastomosis. Note the largely extrinsic component of the recurrence. **C.** Advanced recurrent rectal carcinoma (T4bN1M0). The rectal wall is markedly thickened, and a tumor mass is noted to extend to the sacrum (straight arrows) and piriformis muscle on the left (curved arrow). Adenopathy is inseparable from the mass. A rectal tube (open arrow) is also seen on this section.

curative resection, and 80% of these recurrences develop within the first 2 years,²⁰⁴ early and frequent follow-up studies are recommended. Many cancer centers observe a frequent follow-up program that includes serum CEA level determination, chest radiography, colonoscopy, and imaging.^{185,205} The most commonly recommended sequence of imaging follow-up studies consists of baseline CT or MRI at 3 to 4 months, with subsequent imaging examinations at 6-month intervals for 3 years and then at yearly intervals for 5 years. PET/CT has proven that it can distinguish between surgical scar and tumor recurrence with a high degree of accuracy.⁴⁷

Computed Tomography

Early studies established the usefulness of CT in detecting local recurrence and metastases to lymph nodes, liver, peritoneal cavity, retroperitoneum, and lung.^{206,207} Sensitivities as high as 93% to 95% were initially reported for the detection of locally recurrent tumor.^{208,209} Later investigations indicated accuracy rates ranging from 53% to 88%.^{205,210-212} Most diagnostic errors are a result of the inability to detect microscopic invasion of perirectal or pericolic fat in patients with reanastomoses, assess presence or absence of metastatic foci in normal-sized lymph nodes, and visualize minimal local tumor recurrence at the anastomotic site, particularly if the postoperative scar has not changed in size.

The CT features of recurrent anastomotic tumor are similar to those of the primary tumors, but the recurrence may be largely extrinsic. MDCT often can demonstrate the staple line at the anastomosis (Fig. 59-44). In these patients, wall

Figure 59-45 Postsurgical scar in patient with total abdominoperineal resection. A small area of soft tissue density (arrows) is seen in the presacral region.

thickening caused by plication defects must be differentiated from recurrent tumor. The presence of streaky densities or a clean operative bed suggests fibrosis, whereas the presence of a mostly globular mass favors the diagnosis of tumor recurrence.⁸⁷ However, other studies have indicated that a globular soft tissue mass may represent granulation tissue, hemorrhage, edema, or fibrosis in the early postoperative period (Fig. 59-45 and Box 59-2).⁹³ Postradiation fibrosis can also cause streaky densities or a presacral mass.^{208,213,214} Pelvic radiation causes an inflammatory reaction in the soft tissue of the pelvis, which

BOX 59-2 DIFFERENTIAL DIAGNOSIS OF COLORECTAL MASS WITH SOFT TISSUE STRANDING

Neoplasm (primary and secondary)
 Focal colitis (e.g., ameboma, Crohn's disease, neutropenic colitis)

 Peritonitis with infected fluid in pouch of Douglas

leads to increased fat attenuation and thickening of the perirectal fascia. These changes persist for many years and may be indistinguishable from tumor recurrence. In a study that compared CT with PET, presacral soft tissue masses were seen by CT in 48% of patients with suspected tumor recurrence, and these findings were caused by actual tumor recurrence in only 23%.⁴⁷

Benign postoperative masses may persist on CT more than 24 months after abdominoperineal resection.²¹⁴ A baseline CT study 3 to 4 months after surgery frequently demonstrates the presence of a mass, which by 4 to 9 months decreases in size and develops sharper margins. In the absence of symptoms and elevated CEA titers, this change in the appearance of the mass should not cause concern about local tumor recurrence. However, any increase in mass size, even in the absence of local invasion, lymphadenopathy, or perineal soft tissue density, should suggest recurrence, prompting percutaneous biopsy (Fig. 59-46).^{213,214} Biopsy results may be negative if the recurrent tumor incites a substantial fibrous reaction.

With TME, the primary tumor is removed together with the perirectal lymph nodes but the internal iliac nodes are left in place. Positive lymph nodes left behind at TME substantially increase the risk for local recurrence in patients with lower rectal cancer. In one study, it was shown that 28% of patients with distal rectal cancers and positive lymph nodes had involvement of the internal iliac nodes, and in 6% these lateral chains were the only nodes involved.²¹⁵ These patients are staged as lymph node–negative at TME. In a large TME trial, it was shown that nodal disease is a prognostic indicator for local recurrence and distant metastases.²¹⁶ Detection of these nodes is essential if preoperative radiation and chemotherapy are considered for patients at high risk for recurrence. If postoperative radiation and chemotherapy is chosen for patients with advanced node-positive disease, preoperative detection of positive lymph nodes is not as crucial.

For 2 decades, CT was considered the best modality for detecting and staging recurrent rectal or rectosigmoid carcinomas. In patients who have had sphincter-saving resection of rectal and rectosigmoid carcinomas, almost all recurrent tumors develop extraluminally and subsequently infiltrate the suture lines. These extraluminal recurrences are missed on endoscopy and barium enema. In these patients, the rectum must be

Figure 59-46 CT scan of recurrent rectal mass in patient after total abdominoperineal resection. **A.** Irregular soft tissue mass (arrows) is identified in the rectal bed. Size of mass has increased slightly compared with baseline CT study obtained 1 year before present examination. **B.** Percutaneous biopsy confirms presence of recurrent tumor. Short arrows outline the needle, with its tip in the mass of recurrent tumor (arrow).

distended with negative contrast material to detect subtle lesions.²¹¹ Glucagon helps the patient retain the rectal contrast medium but its administration is optional. More recently, comparison of contrast-enhanced CT with PET revealed CT sensitivities for local tumor recurrence that were lower than those for MRI and PET.^{205,217,218} However, results obtained with MDCT and thin sections in large series are not currently available for local tumor recurrence.

Colonoscopy and barium enemas provide exquisite mucosal detail but cannot assess extraluminal disease and remote metastases. Therefore, barium enema and CT are complementary radiologic methods for evaluating patients with suspected recurrent colon tumor. In patients with abdominoperineal resections, CT and MRI are the primary imaging tests for evaluating recurrent tumor (Fig. 59-47). Definition of the full extent of disease, particularly to distant sites, is necessary if another resection is contemplated.

Magnetic Resonance Imaging

MRI has slightly superior results to CT in detecting recurrent tumor in patients who have undergone a low anterior resection or transanal local excision.^{217,218} In some cases, large surgical clips slightly impair the quality of MRI scans, but CT scans may also be difficult to analyze when large clips are present at an anastomotic site or in an area of lymphadenectomy. After total resection of the rectum, presacral masses are readily detected and staged with MRI. Initial reports have suggested

Figure 59-47 CT scan of recurrent rectal carcinoma with adrenal metastasis (T4bN1M1). **A.** Low-density mass (arrows) is seen in left adrenal gland. A cyst also is present in the right kidney. **B.** Large, irregular mass present in presacral space (arrows) with destruction of sacrum. Air bubbles within the mass indicate necrosis in the absence of clinical evidence of infection.

Figure 59-48 MRI of a postsurgical scar in patient with total colectomy. **A.** T1-weighted spin-echo image (600/11). Area posterior to the bladder has low signal intensity (arrows). **B.** T2-weighted spin-echo image (2500/80). Low signal intensity area on T1-weighted image remains dark (arrows) on T2-weighted scan, suggesting fibrosis in the surgical bed.

that postoperative and postradiation fibrosis have a low signal intensity on T1- and T2-weighted sequences (Fig. 59-48), whereas tumor recurrence has a high signal intensity on T2-weighted images.²¹⁹⁻²²³ However, it now appears doubtful that MRI cannot reliably distinguish among recurrent tumor, fibrosis, and inflammation (Figs. 59-48 and 59-49).^{224,225}

One study using T2-weighted sequences with long repetition and long echo times examined the value of MRI in distinguishing early fibrosis (1 to 6 months after first treatment), tumor or late fibrosis (>12 months), and recurrent tumor.²²⁶ The authors found higher signal intensity values for early fibrosis compared with late fibrosis, probably because of increased vascularity, edema, and the presence of immature mesenchymal cells in granulation tissue. Radiation-induced necrosis and postsurgical inflammatory reaction can also contribute to an increase in signal intensity on T2-weighted images. The increase in tissue fluids seen in granulation tissue and necrosis caused by radiation makes distinguishing early fibrosis from tumor recurrence difficult or even impossible (Fig. 59-50). However, late fibrosis and tumor recurrence could be clearly distinguished from one another (see Fig. 59-48).²²⁴ Other studies found similar results, but one showed that the accuracy of MRI in differentiating between radiation damage and residual or recurrent tumor varied with the primary site.^{100,222,225}

It was excellent for cervical carcinoma but suboptimal for rectal carcinoma.²²⁶

De Lange and colleagues²²⁷ compared MRI results with histologic sections from tissue obtained during radical pelvic exenteration or extensive partial resection of a mass in patients with suspected recurrent rectosigmoid carcinoma. They found that the signal intensities on T2-weighted images do not permit prediction of the histologic diagnosis of a lesion. High signal intensity was found in areas of viable tumor (Figs. 59-51 and 59-51C), tumor necrosis, benign inflammation, and edematous tissue (Fig. 59-52). Because a desmoplastic reaction is a common response to many benign and malignant processes, including tumors of the colon and rectum, areas of low signal intensity on T2-weighted images were also nonspecific, and the differential diagnosis included tumor-induced fibrosis and non-neoplastic, benign fibrotic tissue. However, MRI can reveal a presacral mass accurately and depict its complete extent. If such a mass consists mainly of desmoplastic tissue, with only small strands of interspersed tumor tissue, even a percutaneous biopsy specimen may show fibrous tissue alone and no malignant cells. In these cases, a definitive diagnosis may be made by PET, possibly with surgical removal of the mass or biopsy at laparotomy. It has been shown that if the mass enhances with gadolinium (>40%), it most likely represents tumor recurrence

Figure 59-49 MRI scan of recurrent rectal carcinoma after resection and reanastomosis. **A.** T2-weighted fast spin-echo image shows thickened rectal wall (*arrows*), perirectal stranding, and intermediate signal intensity posterior to the rectum (*short arrows*), suggesting tumor recurrence. **B.** T1-weighted spin-echo image nicely demonstrates mural thickening of the rectum (*arrows*). A low signal intensity presacral mass (*arrowheads*) is better depicted than on the T2-weighted image. A thickened rectal wall and poor tissue definition in the presacral space on T2-weighted sequences may be at least in part be caused by postoperative radiation, which leads to edema and fibrosis. **C.** Axial T2-weighted images at higher level than **A** and **B** reveal increased signal intensity in piriformis muscle bilaterally (*thin long arrows*), indicating muscle invasion by a large presacral tumor mass (*large short arrows*).

Figure 59-50 Indeterminate MRI scans of recurrent carcinoma after total colectomy. **A.** T1-weighted spin-echo image (700/20). An area of low signal intensity mixed with some intermediate signal intensity (*arrows*) is seen in the presacral space. **B.** T2-weighted spin-echo image (2500/70). The presacral soft tissue mass has intermediate signal intensity on T2-weighted scans (*arrows*). This is an indeterminate result and could represent recurrent viable tumor with a moderate amount of fibrous stroma, mild tumor necrosis, inflammation, or granulation tissue after surgery, irradiation, or both.

Figure 59-51 MRI scans of recurrent rectal carcinoma.
A. T1-weighted spin-echo image (533/11). An area of low signal intensity (black arrow) representing scar tissue is seen in presacral space. In addition, a slightly irregular, oval mass (white arrows) is seen immediately anterior to piriformis muscle, owing to recurrent tumor.
B. T2-weighted fast spin-echo image (4000/105). Scar tissue (black arrow) is clearly identified as an area of low signal intensity, and the recurrent tumor mass (white arrow) has intermediate signal intensity.
C. T1-weighted spin-echo image with fat suppression. Scar tissue remains largely dark, but the recurrent tumor and the uterus (u) demonstrate increased signal intensity.
D. T1-weighted spin-echo image after gadolinium (533/11). Enhancing recurrent mass is slightly larger 3 months later (arrows).

if the patient is at least 1 year postsurgery or irradiation.²²⁸ Nevertheless, published result with gadolinium enhancement are conflicting.^{217,229}

One MRI study demonstrated good distinction between scar tissue and recurrence based on measurements of the time-intensity curve and the ratio of signal intensity of the lesion to the signal intensity of the iliac artery at 60 seconds, but not for the maximum change in signal intensity as other studies have demonstrated.²²⁹ Whether an MR perfusion study can be used to distinguish between tumor recurrence and scar tissue remains to be seen. One study using MDCT with kinetic scanning and maximum density measurements did not show a significant difference between patients with and without tumor recurrence.²³⁰ However, CT perfusion studies in primary rectal tumors to assess response to chemotherapy and irradiation have shown promising results.^{231,232} In one prospective study, diffusion-weighted MRI with measurement of apparent diffusion coefficient (ADC) values was valuable in distinguishing between local recurrence of colorectal neoplasms and post-therapeutic soft tissue changes, except in mucinous adenocarcinomas, in which the high ADC values could be confused with benign lesions.²³³

MRI is a sensitive method for detecting masses after colorectal surgery, and its specificity is slightly higher than that of CT.²¹⁷ In these patients, benign and malignant processes cannot be distinguished solely on the basis of morphologic appearance and signal intensity on MRI scans. MDCT may be more helpful in evaluating anastomoses in patients with suture material or

multiple clips from lymphadenectomies because susceptibility artifacts may be problematic at a high magnetic field strength. MDCT may be more valuable than MRI for the detection of nonlocal recurrence, but more studies are needed to determine the efficacy of these procedures and their possibly complementary natures. Further technical advances may improve MRI results.

Transrectal Ultrasound

The findings and results of TRUS for recurrent colorectal malignancy are similar to those for primary carcinoma, but the examination can be done only for patients who have had a transanal local excision, low anterior resection or, in women, an abdominoperineal resection. In patients with total abdominoperineal resection and colostomy, the recurrent tumor should be assessed by CT, MR, PET, or scintigraphy with MoAb.

TRUS provides a highly accurate assessment of local recurrence. In one study, TRUS revealed all 15 recurrences of rectal neoplasm.²³⁴ In four cases, CEA titers were not elevated, and rectal or vaginal digital examination, rigid rectoscopy examination, and pelvic CT scans were negative. In these four patients, TRUS was the only method that detected recurrence. Therefore, endoluminal sonography should be used for evaluating patients when early or limited recurrence is suspected or the patients had a tumor grade or stage with a high prognostic factor for recurrence, even if the results of initial tests in routine follow-up examinations are negative.

Figure 59-52 MRI scans of recurrent rectal carcinoma. **A.** T1-weighted spin-echo image (500/14) demonstrates ill-defined area of low signal intensity (arrows) mixed with small regions of higher signal intensity in patient 4 months status post-abdominoperineal resection. **B.** T1-weighted image (533/14) after gadolinium. The previously identified area (arrows) in the presacral space clearly enhances. This could represent postoperative inflammation or early recurrence. **C.** T2-weighted fast spin-echo image (4500/105). The area of low signal intensity on the T1-weighted image now shows mostly high signal intensity. Given the short interval after resection, this most likely represents postsurgical changes. SV, seminal vesicles.

Immunoscintigraphy

Most results of MoAb immunoscintigraphy have been for patients with primary colorectal tumors, and only studies of small numbers of patients with recurrent or residual tumor have been published.^{148-150,159} In one study using ¹¹¹In-labeled MoAb ZCE-025,¹⁵⁰ recurrences were found in 79.4% of 16 patients, and immunoscintigraphy was beneficial for their management (Fig. 59-53). Other immunoscintigraphic studies that focused on recurrent colorectal tumor showed similar sensitivities, with a high negative predictive value.^{150,159,235} One study compared the sensitivity and specificity of imaging with a ^{99m}Tc-labeled Fab fragment of anti-CEA IMMU-4 with that achieved with CT for detecting pelvic recurrence of colorectal tumor.²³⁶ The sensitivity and specificity for antibody scanning alone was 79% and 84% and improved to 83% and 81% when combined with CT, but did not reach statistical significance.

Positron Emission Tomography

PET has been used extensively for assessing patients with suspected recurrence or residual tumor from colorectal neoplasms. In several studies, the distinction between neoplasm and scar tissue was made with a high degree of accuracy, with lesion-to-soft tissue ratios of 1.19 to 4.94.¹⁶⁶ However,

Figure 59-53 Immunoscintigraphy of recurrent rectal carcinoma. A large mass of high uptake (arrows) is seen in the pelvis of a patient with recurrent rectal tumor.

Figure 59-54 PET/CT scan of recurrence of tumor at the anastomosis in the rectosigmoid colon. This patient had undergone resection for sigmoid carcinoma and presents now with rising CEA levels. **A.** MDCT scan in the pelvis obtained in the axial plane demonstrates the partially necrotic recurrent tumor with a large extrinsic component (*large arrows*). The staple lines (*short arrows*) are also seen. **B.** The corresponding fusion image demonstrates markedly increased FDG uptake of the recurrent tumor at the anastomosis (*arrows*) but not in the necrotic component (*short arrow*). **C.** The coronal fusion image again demonstrates local recurrence (*long arrows*). A low-attenuation lesion seen on CT in the dome of the liver (*short arrow*) was not positive for a liver metastasis.

based on the FDG differential absorption ratio values, one patient was misclassified because of low FDG uptake. All scars in the pelvis after abdominoperineal resection were correctly identified. In another study, in five patients whose CT and PET results were similar, three recurrences and two scars were correctly identified.¹⁶⁷ In four patients with negative or equivocal CT scans, PET correctly identified all tumors and, in three patients whose CT scans raised suspicion of recurrence, PET correctly excluded recurrence. Other studies have confirmed these early results.²¹² PET appears to have an advantage over CT in the detection of recurrent hepatic metastases after partial hepatectomy, extrahepatic metastases, and local recurrence (see Fig. 59-54).²¹² In one study comparing PET alone to PET/CT, the sensitivity, specificity, and overall accuracy of PET in diagnosing intra-abdominal extrahepatic recurrence of colorectal cancer were 82%, 88%, and 86%, respectively, which was lower than 88%, 94%, and 92%, respectively, reported for PET/CT.²³⁷ It appears that PET/CT is an accurate method for detecting recurrent colorectal neoplasms (Fig. 59-55) and may offer an alternative to biopsy because it successfully excludes recurrence in patients with suspicious masses in the surgical bed. Nevertheless, larger series are needed to confirm these results.

Cross-Sectional Imaging in Recurrent Colorectal Carcinoma

Based on current literature, it is difficult to compare CT and MRI, used alone or in combination, for the detection of recurrent disease. This difficulty is mainly because of the great variations in both techniques and types of scanners used, scanning protocols, and methods of administering the contrast agent. Even the diagnostic criteria, study population, and analysis of the data vary greatly. Although MRI demonstrates excellent results for local tumor recurrence detection, especially if diffusion-weighted sequences were included, results of MRI combined with FDG-PET are not yet available. CT has the major advantage that the entire abdomen and pelvis can be scanned within a few seconds, much shorter than the acquisition time for an abdominal and pelvic MR study.

Based on currently available data, it appears that a combination of CT and PET would be most beneficial for imaging of possible recurrent colorectal tumor. CT should be performed with contrast enhancement. Any suspicious area on CT can thus be clarified by PET. If PET/CT is not available, CT or MRI combined with immunoscintigraphy could be helpful. All these imaging protocols should be accompanied with frequent

Figure 59-55 PET/CT scans of recurrent colon carcinoma. Shown is a patient with a history of colon carcinoma and hepatic metastases that were treated with partial right hepatectomy, hepatic arterial infusion pump therapy, and radiofrequency ablation. **A.** MDCT scan of thorax in axial plane shows nodule (arrow) in right lower lobe. **B.** Axial fused PET/CT scan demonstrates mildly increased FDG uptake (standardized uptake value [SUV], 2.4) in this nodule (arrow) consistent with pulmonary metastasis. **C.** MDCT scan of the abdomen in the axial plane shows a low-density mass with a peripheral enhancing rim (arrows) in the posterosuperior segment of the liver suggestive of tumor recurrence in the periphery of a treated metastasis with central necrosis. **D.** Fused coronal PET/CT scan demonstrates a large lesion in right lobe of liver (arrows), with doughnut-shaped peripheral area of elevated FDG uptake (maximum SUV, 9.6). This appearance is consistent with tumor recurrence after ablation.

clinical visits, laboratory tests (serum CEA levels), and colonoscopy, where feasible. In general, MRI is used in selected cases and is not recommended for routine follow-after curative resection for colorectal cancer.^{127,238,239}

Because of the high frequency of tumor recurrence in the first 24 to 36 months after surgery, a series of follow-up CT examinations at 6-month intervals should be obtained to detect early tumor recurrence.¹⁷³ In addition, a CT scan is indicated whenever a patient has a rising CEA titer or symptoms. Because local recurrence of cancer occurs in 50% of patients within the first year and in 80% within the second year,¹⁹² patients with suspected recurrence should have a baseline study 3 to 4 months after initial surgery. This time frame is chosen because

postsurgical acute changes, such as edema and hemorrhage, have substantially resolved. Follow-up examinations should be compared with those of the baseline study to avoid unnecessary biopsies. A study is considered positive if masses or nodes are detected that were not seen on the baseline study or have become larger since the original study. Biopsy specimens should be obtained of any new or enlarging mass or lymph nodes or confirmed with PET. Any clinical signs, elevated CEA levels, or suspicious CT or MRI findings should lead to a FDG-PET examination for further evaluation to ensure early detection of recurrence, with possible curative resection. If CT or MRI diagnoses resectable recurrence of colorectal tumor that is confirmed by PET, a biopsy should be avoided for fear of tumor seeding.

Embolic Metastases

This chapter discusses a variety of benign and malignant tumors of the colon as separate entities. Although these tumors are associated with a wide range of clinical and radiologic manifestations, they may have typical features on imaging studies that suggest the correct diagnosis.

Lymphoma

PATHOLOGIC FINDINGS

Malignant lymphomas involve the gastrointestinal (GI) tract as primary neoplasms or as part of a disseminated disease. The colon is the third most common primary site of lymphoma involving the GI tract (after the stomach and small bowel); colonic involvement occurs in 6% to 12% of cases.¹⁻³ Primary lymphoma of the colon is rare, comprising less than 1% of all primary malignant tumors of the colon.^{4,5} Colonic involvement by systemic lymphoma is relatively common, with microscopic

evidence of tumor in up to 44% of cases at autopsy.³ Non-Hodgkin's lymphoma accounts for almost all colonic lymphomas; Hodgkin's lymphoma involving the colon is extremely rare.^{1,6,7} Primary colonic lymphoma is usually a B-cell lymphoma; diffuse large B-cell lymphoma is the most common primary colonic subtype.²

CLINICAL FINDINGS

Primary non-Hodgkin's lymphoma involving the colon is usually seen in middle-aged or older persons.² Men are more frequently affected than women by a ratio of 2:1.^{6,8} Abdominal pain, weight loss, and altered bowel habits occur in 60% to 90% of patients, and rectal bleeding or diarrhea occur in 25%.^{6,9} A palpable abdominal mass is the most frequent physical finding.⁶ Long-standing ulcerative colitis appears to be a predisposing condition, but the development of lymphoma in these patients may be related more to treatment with immunosuppressive agents than to the disease itself.^{6,8,10,11} Extranodal presentation of post-transplantation lymphoproliferative disorders is typical, and B-cell lymphomas may arise in the colon after solid organ transplantation.¹² Anorectal lymphoma is seen in HIV-infected patients, but this has been decreasing in frequency.¹³

RADIOGRAPHIC FINDINGS AND DIFFERENTIAL DIAGNOSIS

The primary form of colonic lymphoma usually involves the ileocecal valve, cecum, or rectum.¹²⁻¹⁵ In contrast, systemic lymphoma usually involves the entire colon or long segments of bowel.^{7,16-18} The primary localized form of colonic lymphoma may be manifested by a variety of radiographic findings, including a polypoid or cavitory mass or circumferential mural lesion. Bulky polypoid masses represent the most common form of primary colonic lymphoma.^{5,9,18-20} These tumors usually appear as smooth-surfaced, broad-based sessile lesions, with or without central depressions or ulcerations.¹⁴ These lesions vary from 4 to 20 cm in size and are usually located near the ileocecal valve (Fig. 60-1).¹⁵ Extension of cecal lymphoma into the terminal ileum is not uncommon (see Fig. 60-1).

The annular infiltrating form of colonic lymphoma usually involves a long segment of colon, appearing as a concentric area of narrowing or as a cavitory mass (Fig. 60-2).^{5,20} Although the colonic lumen may be narrowed, obstruction is uncommon. The infiltrating form is usually characterized by a discrete lesion, with thickened, irregular haustral folds and a nodular surface pattern. Although the contour is irregular, the mucosal surface is smooth, suggesting submucosal infiltration rather than mucosal ulceration. Thus, the major considerations in the differential diagnosis of the annular infiltrating form of lymphoma include submucosal hemorrhage and edema (caused by ischemia or a bleeding diathesis) and an unusual colonic carcinoma.⁵

Large infiltrating tumors may extend into the mesentery or exhibit central cavitation, resulting in a bulky, cavitary mass lesion. The major considerations in the differential diagnosis of the cavitary form of lymphoma include a perforated colonic carcinoma and a mesenchymal tumor, such as a GI stromal tumor.

Figure 60-1 Lymphoma of the terminal ileum and ileocecal valve. Spot image from a small bowel follow-through shows a smooth-polypoid fold (arrow) in the terminal ileum and a coarsely lobulated mass (small arrows) replacing the ileocecal valve.

The diffuse multinodular form of colonic lymphoma (lymphomatous polyposis) is associated with disseminated disease from a nodal primary lymphoma or occurs as a true primary GI lymphoma. Histologically, this form of lymphoma is usually a mantle cell lymphoma derived from a subpopulation of mantle zone cells.^{21,22} These multinodular lymphomas involve long segments of the colon or the entire colon. The small intestine may be simultaneously involved. The tumors disseminate rapidly to the liver, spleen, peripheral lymph nodes, and bone marrow.²² More than 100 nonuniform, smooth, sessile nodules varying from 2 to 25 mm in size carpet the colonic surface.^{15,19} The nodules are occasionally elongated, pedunculated, umbilicated, or filiform.¹⁹ A conglomerate cecal mass is seen in almost 50% of cases.¹⁹ Associated mesenteric lymph nodes are usually enlarged.²² The multinodular form of colonic lymphoma may be confused radiographically with familial polyposis, lymphoid hyperplasia, inflammatory bowel disease, or infectious diseases, such as pseudomembranous colitis or schistosomiasis. The nodules of colonic lymphoma are nonuniform and relatively large in comparison to the uniform, 1- to 2-mm nodules of lymphoid hyperplasia. Unlike the pseudopolyposis in inflammatory bowel disease, the haustral pattern is also preserved in colonic lymphoma, and ulceration is uncommon.^{7,15} Conglomerate cecal masses are more frequent in disseminated lymphoma than in the polyposis syndromes.^{7,19} Rarely, diffuse colonic lymphoma may be associated with acute toxic dilation or pneumatosis coli.¹⁵

Vascular Lesions

HEMANGIOMA

Clinical and Pathologic Findings

Hemangiomas of the colon are rare vascular lesions, but the radiologic diagnosis is important because these lesions may be misdiagnosed at endoscopy and have a high mortality rate related to severe GI bleeding.²³ Patients with colonic hemangiomas usually present at a young age with acute, recurrent, or chronic rectal bleeding.^{24,25} Some patients may have severe,

Figure 60-2 Lymphoma of the transverse colon. **A.** Spot image from a double-contrast barium enema shows a long (limits denoted by open arrows) concentric lesion in the transverse colon, with an irregular contour. Note protrusion of the contour superiorly outside the expected lumen of the bowel (arrow); this finding indicates cavitation of the mass. **B.** CT scan shows a large soft tissue mass (arrows) with lobular thickening of the walls of the transverse colon.

life-threatening rectal bleeding²⁵; mortality rates for this tumor approach 50%.²⁶ Obstructive symptoms and diarrhea are uncommon, occurring in 15% to 20% of cases.^{24,27} Occasionally, patients with anorectal lesions may complain of tenesmus or constipation.

Cavernous hemangiomas are the most common form; capillary hemangiomas are second in frequency.^{27,28} Cavernous hemangiomas are unencapsulated lesions, usually arising in the submucosa. They are composed of large, multiloculated, thin-walled vessels²⁶ separated by loose connective tissue. They usually occur in the rectum or sigmoid colon,²⁹ appearing as discrete submucosal masses²⁷ or, more frequently, as diffuse, infiltrative lesions.²⁵ Polypoid tumors may intussuscept, causing obstruction, whereas infiltrative lesions often ulcerate and bleed.²⁵

Capillary hemangiomas usually occur as solitary, sharply circumscribed submucosal masses in asymptomatic patients. The tumors are composed of small vessels lined by well-differentiated endothelial cells.²⁶ The vessels are packed together, with scant surrounding connective tissue. These tumors are occasionally associated with cutaneous or visceral hemangiomas.^{25,30} Colonic hemangiomas may occur in the Klippel-Trenaunay syndrome, manifested by the triad of cutaneous hemangiomas, soft tissue hypertrophy of the involved lower extremity, and congenital varicose veins.^{29,31} Cavernous hemangiomas of the colon are also seen in the blue rubber bleb nevus syndrome and in some patients with Peutz-Jeghers syndrome.³² Hemangiomas have also been reported in 5% to 8% of patients with Turner's syndrome.³³ Colonic hemangiomas have no propensity for malignant transformation and should therefore be distinguished from their true neoplastic counterpart, angiosarcomas.

Radiographic Findings and Differential Diagnosis

Rectal hemangiomas are frequently misdiagnosed on endoscopy as hemorrhoids or proctitis.^{26,34} As a result, the radiologist may be the first physician to suggest the correct diagnosis. Plain abdominal radiographs may show multiple phleboliths along the course of the bowel in 50% of cases.^{25,26,30} Hemangiomas should therefore be suspected if abdominal radiographs demonstrate phleboliths in young patients with GI bleeding or clusters of phleboliths in atypical locations or along the expected course of the rectosigmoid colon.

Barium enema examinations usually reveal a circumferential lesion, with scalloped contours and a nodular mucosal surface pattern.²⁵ The colonic lumen is narrowed in 50% of cases. If the tumor is in its usual rectosigmoid location, a wide presacral space may be seen. If phleboliths are visible, they are seen in the expected location of the colonic tumor (Fig. 60-3).²⁹ The polypoid form of hemangioma is usually manifested by smooth, sessile, broad-based submucosal masses.

Although hemangiomas are usually vascular at angiography, they may occasionally be hypovascular or avascular because of vessel thrombosis and sclerosis.²³ Computed tomography (CT) better delineates the true dimensions of the mass (see Fig. 60-3) and involvement of adjacent structures, such as the urinary bladder.³⁰ Hemangioma is included in the differential diagnosis of polypoid submucosal masses, but the most common submucosal mass in the colon is a lipoma. Hemangioma is also included in the differential diagnosis of infiltrative submucosal rectosigmoid lesions, such as those found in solitary rectal ulcer syndrome or lymphoma. However, the clinical history and presence of phleboliths should suggest the correct diagnosis.

Figure 60-3 Hemangioma of the colon. CT scan shows lobulated thickening of the circumference of the wall of the cecum with numerous calcified phleboliths (arrows) in the subserosa.

LYMPHANGIOMA

Lymphangiomas of the colon are extremely rare benign lesions of neoplastic or hamartomatous origin.³⁵ The lesions are composed of a cluster of lymphatic spaces lined by endothelial cells and separated by connective tissue septa.³² These dilated lymphatics are usually found in the muscularis mucosae or submucosa. Some lymphangiomas arise in the colonic mesentery.³⁶ Patients with colonic lymphangiomas usually present in the fourth to sixth decade of life with abdominal pain, rectal bleeding, watery diarrhea, and/or altered bowel habits.^{36,37} Lymphangiomas may appear radiographically as solitary, 2- to 4-cm, often pedunculated polypoid lesions³⁷ or as smooth submucosal masses.^{35,38} These soft tumors are pliable, changing in size or shape with compression or varying luminal distention, and they may be compressible during endoscopic ultrasound.³⁹ A cystic or multicystic mass is often found on endoscopic ultrasonography or CT. The smooth unilocular or multilocular submucosal mass is of water attenuation (0-20 HU) on CT.^{39,40}

ANGIODYSPLASIA

Clinical and Pathologic Findings

Angiodysplasia is a common cause of chronic low-grade or acute massive lower GI bleeding in older patients.^{41,42} These lesions are acquired vascular ectasias, possibly caused by chronic, low-grade colonic obstruction.⁴¹ Angiodysplasias are composed of clusters of dilated, tortuous, thin-walled veins,

venules, and capillaries localized in the colonic mucosa and submucosa. The mucosal layer overlying the vascular tuft may be thin or ulcerated. These lesions are single or multiple and small (usually <5 mm), usually found in the cecum or ascending colon.⁴¹

Angiodysplasias may coexist with other causes of GI bleeding. These lesions have been found at autopsy in 2% of asymptomatic older patients and, in one series, angiodysplasias were present in the resected specimens in 12 of 15 patients who had undergone surgery for colonic carcinoma.⁴¹ Angiodysplasias are not associated with angiomatous lesions of the skin or other viscera.⁴¹

Radiographic Findings

Angiodysplasias may be detected during the work-up of patients with severe or recurrent lower GI bleeding after a normal barium enema or colonoscopy.⁴² During the arterial phase of angiography, a focus of angiodysplasia usually appears as a tangle of small vessels at the end of a cecal or right colonic artery. Early filling of draining veins with contrast medium is usually seen, but extravasation of contrast medium rarely occurs.⁴³ The radiologist is critical to the diagnosis of angiodysplasia because the surgeon is unable to see or palpate these lesions during surgery. The pathognomonic histologic findings are not usually present on endoscopic biopsy specimens. As a result, the decision for surgery is made on the basis of the radiographic findings and the clinical history of severe or recurrent lower GI bleeding.

KAPOSI'S SARCOMA

Kaposi's sarcoma involving the colon usually occurs in patients with AIDS. Kaposi's sarcoma has also been reported in HIV-negative patients with Crohn's disease or ulcerative colitis and in patients who have undergone solid organ transplantation.^{44,45} Colonic Kaposi's sarcoma is associated with human herpesvirus 8 infection. Kaposi's sarcoma in the colon is manifested radiographically by a flat or plaque-like lesion, small polypoid nodule, or polypoid submucosa-appearing mass, with or without central umbilication.³² The tumor is usually confined to the mucosa and submucosa.

Endocrine (Carcinoid) Tumors

PATHOLOGIC FINDINGS

Endocrine cells are scattered throughout the GI tract. These cells synthesize and secrete a variety of peptide hormones and biogenic amines. The endocrine cells give rise to GI tumors traditionally termed *carcinoid tumors* but now preferably termed *endocrine cell tumors*. The most common sites of endocrine cell tumors include the appendix (35%), ileum (16%), lung (14%), and rectum (13%).⁴⁶ Endocrine cell tumors arising in the remainder of the colon constitute only 2% to 3% of all carcinoid tumors.⁴⁶⁻⁵⁰

The most common sites of endocrine cell tumors in the colon are the rectum and cecum. Endocrine tumors involving the cecum and ascending or transverse colon are of midgut origin. These midgut lesions may synthesize, store, and secrete serotonin. Although serotonin may be produced, carcinoid syndrome is rare.⁵¹ If carcinoid syndrome is present, it is usually associated with liver metastases.

Hindgut endocrine cell tumors involve the descending colon, sigmoid colon, and rectum. They primarily synthesize and store a variety of polypeptide hormonal substances, including gastrin, somatostatin, glucagon, and vasoactive intestinal polypeptide.^{47,52} These tumors do not usually produce serotonin or cause carcinoid syndrome.

ENDOCRINE CELL TUMORS OF THE RECTUM

Endocrine cell tumors arising in the rectum are usually small, smooth, submucosal polypoid lesions less than 2 cm in diameter and are located in the lower two thirds of the rectum. Most cases are discovered incidentally during a screening barium enema examination or endoscopy or during work-up for rectal pain or bleeding.^{53,54} Small rectal carcinoids have low malignant potential and are cured by simple and complete excision. As with any carcinoid tumor, the larger the tumor, the greater the chance of metastases at the time of diagnosis. Although rare, large rectal endocrine cell tumors are associated with a much greater frequency of metastases at the time of diagnosis.⁵⁴ Large rectal carcinoids may appear as irregular ulcerated masses.⁵⁴ If all rectal endocrine cell tumors are considered, patients with rectal carcinoids have an overall 5-year survival rate of about 85%.^{46,54}

ENDOCRINE TUMORS (EXCLUSIVE OF THE RECTUM)

Endocrine cell tumors of the remainder of the colon have a very different clinical history, morphology, and prognosis than small low-grade endocrine tumors of the rectum. Endocrine cell tumors in the colon (exclusive of the rectum) are usually large aggressive lesions associated with a poor prognosis. Patients usually present in the sixth decade of life with symptoms similar to those of colonic adenocarcinoma, including abdominal pain, distention, and a palpable abdominal mass. Rectal bleeding and diarrhea are seen in approximately one third of patients.⁵⁵

Endocrine cell tumors of the colon are usually located in the cecum or ascending colon.^{51,55} These tumors appear on barium enemas as large (>5 cm), fungating intraluminal masses or as irregular annular lesions (Fig. 60-4)^{48,51,56} that are indistinguishable from those of colonic carcinoma. In other patients, these endocrine cell tumors may appear as smooth, polypoid submucosal masses. At the time of diagnosis, 50% to 60% of patients with large endocrine tumors have metastases to the liver, lymph nodes, mesentery, or peritoneum.^{46,51,55} Overall, 5-year survival rates of approximately 50% have been reported.⁴⁶

Fatty Lesions

LIPOMA

Clinical Findings

Colonic lipomas are benign uncommon lesions, occurring at autopsy in less than 1% of patients.⁵⁷⁻⁵⁹ Colonic liposarcomas are exceedingly rare. However, the colon is the most frequent site of GI involvement by lipomas.^{60,61} Most patients are asymptomatic, and the tumors are detected during studies performed for symptoms ultimately attributed to other causes.^{57,59} When these patients are symptomatic, they usually present with

Figure 60-4 Endocrine carcinoma of the colon. Spot image from a double-contrast barium enema shows a short annular lesion (arrow) with shelflike margins in the hepatic flexure of the colon. These radiographic findings are similar to those of an annular carcinoma of the colon, but the mucosa is smoother than that usually found with an annular carcinoma. (Courtesy Seth N. Glick, MD, Philadelphia.)

Figure 60-5 Lipoma of the descending colon. Spot image from a double-contrast barium enema shows a 3-cm, smooth-surfaced, submucosal mass (arrows) with a slightly lobulated contour.

abdominal pain and discomfort.⁵⁹ Rectal bleeding and pain related to intussusception are less common.

Pathologic Findings

Most colonic lipomas are found in the right colon, and 90% originate in the submucosa.^{14,57,59} The remaining 10% arise in the appendices epiploicae. Multiple tumors are found in up to 25% of patients.⁵⁹ Colonic lipomas are usually smaller than 3 cm in diameter, but those that cause symptoms tend to be larger lesions.

Colonic lipomas are encapsulated masses of mature adipose tissue usually confined to the submucosa. Approximately two thirds of these tumors are pedunculated, with a broad-based pedicle covered by normal colonic mucosa. Because of this pedunculation, local trauma and mechanical irritation may lead to focal ulceration and fat necrosis. Continuing inflammation may cause fibrosis and calcification.

Radiographic Findings

Colonic lipomas usually appear on barium enemas as smooth, sessile submucosal masses or as smooth polypoid lesions on a broad-based pedicle (Fig. 60-5).¹⁴ Lipomas may be round, ovoid, or pear-shaped. They are sharply demarcated masses that form obtuse angles with the adjacent colonic wall.⁶² Although these lesions may have a lobulated contour, the mucosal surface is smooth (see Fig. 60-5). Because of the pliable nature of fat, lipomas change shape with palpation, position of the patient,

or varying degrees of colonic distention.^{58,62} These tumors may also elongate during colonic spasm or after colonic evacuation. Some lipomas may serve as the lead point for colocolic intussusceptions.⁶³⁻⁶⁵

Before the advent of CT, the barium enema was considered to be a relatively accurate test for the diagnosis of colonic lipoma.^{62,66} However, a definitive diagnosis of a colonic lipoma can be made on CT when it shows a mass of uniform fat density (60-120 HU) without septa or other large areas of nonfatty tissue (Fig. 60-6).^{39,65,67-69}

When colonic lipomas intussuscept, they can ulcerate and undergo fat necrosis, resulting in CT attenuation numbers higher than those of fat. As a result, an intussuscepting lipoma appearing as a soft tissue mass or having only a small focus of fat attenuation may be confused with an intussuscepting carcinoma.⁶⁵ The radiologist can also confuse any intussuscepting tumor with a lipoma if the eccentrically invaginating mesenteric fat associated with the intussuscepting tumor mass is mistaken for the fat of a lipoma.⁶⁵ Lipomas can also be diagnosed via endoscopic ultrasound as smooth hemispheric polyps with a broad base containing hyperechoic tissue or tissue of intermediate echogenicity.³⁹

FATTY INFILTRATION OF THE ILEOCECAL VALVE

Pathologic, Clinical, and Radiographic Findings

Fatty infiltration (also known as lipohyperplasia or lipomatous infiltration) of the ileocecal valve results from a localized

Figure 60-6 Lipoma of the cecum. CT scan shows a 1.5-cm, smooth-surfaced, ovoid mass (arrow) in the cecum with the same attenuation value as nearby mesenteric fat.

massive accumulation of submucosal fat in this region. The lack of a capsule differentiates this fatty proliferation pathologically from a true lipoma.^{28,70} Fatty infiltration of the ileocecal valve is associated with obesity.²¹ The diagnosis is suggested on barium enema when there is a large ileocecal valve with smooth or lobulated contours and a smooth mucosal surface without a discrete polypoid mass. Although rigid measurements are not reliable in distinguishing a normal-sized ileocecal valve from an enlarged valve, some investigators have suggested that a normal ileocecal valve should be 4 cm or less.⁷¹ Others have found that one lip of a normal valve should be 1.5 cm or less.⁷² A normal ileocecal valve may also have stellate folds radiating toward its center.⁷²

Differential Diagnosis

The radiologist must first decide whether the polypoid projection in the cecum arises on or near the ileocecal valve or actually represents the valve. The normal ileocecal valve is usually located at the level of the first complete haustral fold on the medial or posterior colonic wall at the junction of the cecum and ascending colon.⁷² Filling of the terminal ileum with barium confirms the location of the ileocecal valve. If an ileocecal valve is mildly enlarged (>4 cm) and has a smooth or slightly lobulated contour and smooth mucosal surface, the most likely diagnosis is fatty infiltration of the valve (Fig. 60-7). In contrast, a focal polypoid projection from the ileocecal valve may represent a tumor, such as an adenoma or lipoma (Fig. 60-8).⁷² Any

Figure 60-7 Fatty infiltration of the ileocecal valve. Close-up view from a right side-down decubitus overhead radiograph of the colon shows smooth, slightly lobulated enlargement of the ileocecal valve (arrows). Fatty infiltration was confirmed at colonoscopy performed for other reasons.

mucosal surface irregularity of the ileocecal valve should also suggest the possibility of tumor involving the valve, including an adenocarcinoma. The ileocecal valve may also be involved by Crohn's disease or lymphoma. In Crohn's disease, there is fatty hypertrophy of the valve, usually associated with other radiographic findings of Crohn's disease in the terminal ileum and ileocecal fistulas. In lymphoma, the ileocecal valve is moderately enlarged and has a lobulated contour, usually because of the spread of lymphoma from the terminal ileum.

Stromal Tumors

PATHOLOGIC FINDINGS

Historically, most spindle and epithelioid cell tumors of the GI tract have erroneously been termed *smooth muscle tumors* (leiomyoma or leiomyosarcoma). Only a small percentage of all spindle cell tumors, however, are recognized as arising from smooth muscle cells or neural cells by ultrastructural or immunohistochemical means.⁷³⁻⁷⁶ Most spindle cell tumors are undifferentiated stromal neoplasms, termed *gastrointestinal stromal tumors* (GISTs).⁷³⁻⁷⁶ GISTs originate from the interstitial cells of Cajal or a progenitor of these cells. The interstitial cells of Cajal are within the interstices of the muscularis propria. These cells act as a pacemaker, coordinating peristalsis. GIST development depends on a proto-oncogenic receptor, tyrosine kinase (*KIT*). GISTs usually express CD34 and many have been found to

Figure 60-8 Lipoma of the ileocecal valve. A small, smooth-surfaced, submucosal lesion (arrows) is seen arising from the inferior lip of the ileocecal valve (arrowhead).

contain mutations in *KIT*.⁷⁷ The likelihood of recurrent tumor or metastases with GISTs is based on their mitotic index, size, and location.⁷⁸

SMALL STROMAL TUMORS

Only 1% of all GI tumors are of stromal origin, and these tumors are least commonly found in the colon.⁷⁹ Colonic stromal tumors are usually located in the rectum.⁸⁰ In general, there are two macroscopic types of colonic stromal tumors, small polypoid lesions and large bulky masses. Small polypoid lesions may be sessile or pedunculated and usually arise in the rectum. They probably arise from the muscularis mucosae, are histologically benign, and do not recur after excision.⁸¹ These small polypoid lesions are often true leiomyomas of the colon because they demonstrate smooth muscle differentiation by their desmin positivity and ultrastructural characteristics. These tumors are distinct from GISTs and have essentially no malignant potential. These small rectal lesions appear on barium enema as sessile or pedunculated polyps, with a smooth or slightly irregular surface. Small polypoid leiomyomas have also been reported in patients with AIDS.⁸² Multiple small polypoid neurofibromas may be seen in patients with neurofibromatosis (Fig. 60-9).

LARGE STROMAL TUMORS

Large (>2 cm) stromal tumors probably arise from the muscularis propria. They have a high rate of local recurrence (60%), regardless of histologic differentiation, and are associated with

Figure 60-9 Neurofibromatosis of the colon. Spot image from a double-contrast barium enema shows numerous small, smooth-surfaced filling defects (arrows) and hemispheric lines in the descending colon. Neurofibromatosis is a rare cause of colonic polyposis.

a poor prognosis.⁸¹ These bulky lesions are usually found in the rectum, with the remainder evenly distributed throughout the colon. Large stromal tumors may appear on barium enema or CT as annular lesions, cavitating masses with a prominent extraluminal component, or submucosal masses with or without central ulceration (Fig. 60-10). Cavitation may lead to superimposed infection or perforation with abscess formation.⁷⁹ These lesions may be confused radiographically with colonic lymphomas or perforated colonic carcinomas. Stromal lesions typically metastasize to peritoneal surfaces and to the lungs and liver.⁷⁵

Squamous Cell Carcinoma

Squamous cell carcinomas of the colon are extremely rare tumors. Most squamous cell carcinomas arise in the rectum and cause symptoms identical to those of rectal adenocarcinomas.⁸³ Squamous cell carcinomas of the colon should be distinguished from squamous cell carcinomas invading the colon from the anal canal or from squamous mucosa-lined fistulas. These lesions must also be distinguished from squamous cell carcinomas that have metastasized to the colon and from poorly differentiated adenocarcinomas that show focal squamous differentiation. Squamous cell carcinomas have been detected in patients with a history of ulcerative colitis, pelvic irradiation, and schistosomiasis.⁸⁴ Squamous cell carcinoma arising in the anal canal is often seen in patients with HIV infection, hematologic malignancy, and a solid organ

Figure 60-10 Malignant gastrointestinal stromal tumor of the rectum. CT scan shows a large soft tissue mass (white arrows) arising from the left anterolateral wall of the rectum. The mass enhances to the same degree as adjacent muscle. Infiltration of the fat plane between the rectum and seminal vesicles (black arrow) is present. (From Forbes A, Rubesin SE, et al: *Colon II*. In Forbes A, Misiewicz J, Compton C, et al [eds]: *Atlas of Clinical Gastroenterology*, 3rd ed. Edinburgh, Elsevier Mosby, 2005, p 183.)

transplant.⁸⁵ Squamous cell carcinomas may appear on barium enemas as large, bulky, ulcerated masses grossly identical to rectal adenocarcinomas (Fig. 60-11).⁸³ Hematogenous, lymphatic, and local metastases are frequently present.

Cloacogenic Carcinoma

The epithelium at the junction of the anal canal and rectum is composed of squamous and stratified columnar epithelium, as well as scattered goblet cells. This transitional zone has features of both urothelium and squamous epithelium compatible with a cloacogenic origin.⁸⁶ As a result, many tumors in this region were previously termed *cloacogenic carcinomas*. Primary tumors at the anorectal junction are currently classified according to architectural and cellular differentiation indicative of their cellular origin, including terms such as *squamous cell carcinoma*, *basaloid carcinoma*, *transitional cell carcinoma*, *mucoepidermoid carcinoma*, and *adenoid cystic carcinoma*. Most tumors have a mixture of histologic growth patterns. Tumors with squamous differentiation are termed *squamous cell carcinoma*, as noted earlier. Tumors that arise from submucosal glands in this region are salivary gland-type tumors, such as adenoid cystic carcinoma and mucoepidermoid carcinoma. The most common malignant tumor of the anal canal, however, is not of cloacogenic origin but is an adenocarcinoma arising from the rectal mucosa that subsequently invades the anal canal.

Figure 60-11 Verrucous squamous cell carcinoma arising in a condyloma acuminatum. This young woman had been treated for 5 years for perianal, vaginal, cervical, and vulvar condylomata. A spot image of the distal rectum and anal canal from a double-contrast barium enema shows a polypoid mass (white arrows) in the distal rectum and nodular mucosa extending to the anorectal junction (black arrow), with abnormal mucosa distending the anal canal (double arrow).

The transitional zone is an area in which metaplasia and reserve cell hyperplasia occur in a manner similar to that in the transitional zone of the uterine cervix and gastroesophageal junction.⁸⁶ It has therefore been postulated that some tumors arise in this region in areas of chronic inflammation, squamous metaplasia, and reserve cell hyperplasia, resulting in dysplasia and subsequent carcinoma. For example, homosexual men have a high incidence of squamous cell carcinoma of the anus. These tumors are associated with venereally transmitted human papillomavirus.⁸⁷⁻⁸⁹ Other oncogenic viruses, carcinogens in lubricants and cleansers, and mechanical irritation may also play a role.⁸⁷⁻⁹²

Cloacogenic carcinomas have no distinctive gross pathologic or radiologic features. Patients usually present with rectal bleeding or pain or altered bowel habits. These tumors may be flat, infiltrative, annular, or ulcerative lesions with rolled borders. The tumors may appear on barium enema as submucosal masses with a smooth or ulcerated surface, as broad-based, sessile polypoid masses, or as infiltrative lesions (Fig. 60-12).^{93,94}

Metastases to sacral, internal iliac, and common iliac lymph nodes are found in approximately 50% of patients.

Figure 60-12 Basaloid carcinoma. **A.** Lateral view of the rectum shows the infiltrative pattern of cloacogenic carcinoma. The anterior wall of the rectum is moderately flattened and lobulated (*short arrows*), with thickened nodular folds traversing the rectum (*long arrows*). The rectal mucosa is relatively smooth. Focal circumferential extension of tumor around the rectum is seen as flattening of the posterior rectal wall (*open arrow*). **B.** Prone view of the rectum shows mild inbowing and irregularity of the contour of the lateral walls of the rectum (*long arrows*) and thickened nodular folds en face (*short arrows*).

Hematogenous metastases may also result from spread of tumor via the portal venous system and inferior vena cava. Patients with basaloid carcinoma have a 5-year survival rate of approximately 50%.³²

Metastases

Metastases to the colon are not uncommon.⁹⁵ It also is not uncommon for symptoms produced by GI metastases to occur as the initial manifestation of a primary malignancy. Colonic metastases are classified by their mode of dissemination as follows⁹⁶: (1) direct invasion from a contiguous primary tumor or noncontiguous primary tumor; (2) intraperitoneal seeding; and (3) embolic metastases.

Imaging studies may not only identify the lesion as a metastasis to the colon, but also indicate the mode of dissemination and most likely origin of malignancy.⁹⁷ Detection of these

metastases is also important because localized embolic metastases may be resected for cure or for control of complications, such as GI bleeding or obstruction. Recognition of colonic invasion by tumor also enables the surgeon to perform a wider excision or, if necessary, a diverting colostomy.⁹⁸

DIRECT INVASION FROM CONTIGUOUS PRIMARY TUMORS

The most common tumors that directly invade the colon include carcinoma of the ovary, kidney, uterus, cervix, prostate, and gallbladder, as discussed here.

Prostatic carcinoma may spread via Denonvillier's fascia to invade the rectum anteriorly or circumferentially.⁹⁹ Rectal involvement by prostatic carcinoma occurs in 0.5% to 11.5% of patients.¹⁰⁰⁻¹⁰² Affected individuals may present with obstructive symptoms, constipation, or rectal bleeding.¹⁰²

Although the normal prostate abuts the distal rectum, most patients with prostatic carcinoma invading the colon have involvement of the rectosigmoid junction, with distal rectal sparing.^{99,104} Prostatic carcinoma usually spreads cranially to involve the seminal vesicles before invading the rectum posteriorly. Thus, on barium enema examination, early cases may manifest an extrinsic mass effect, predominantly on the anterior border of the rectosigmoid junction. With colonic invasion, mucosal pleating and tethering are seen en face and a spiculated contour is seen in profile. In advanced cases, the rectum is circumferentially narrowed, with a widened presacral space and spiculated contour.^{99-101,103} In some cases, prostatic carcinoma invades posteriorly to involve the lower rectum (Fig. 60-13). The major consideration in the differential diagnosis is direct invasion of the rectum by a contiguous pelvic tumor such as carcinoma of the urinary bladder.

When left-sided ovarian carcinoma directly invades the colon, it first involves the inferior border of the sigmoid colon.¹⁰⁴ Colonic wall invasion is indicated by angulation of the affected sigmoid loops, spiculation of the colonic contour, and tethering and angulation of mucosal folds en face (Fig. 60-14). Rarely, a fistula to the sigmoid colon may be seen.¹⁰⁵

Renal cell carcinoma or recurrent renal cell carcinoma in the retroperitoneum may directly invade the colon.^{96,104,106} Left-sided renal cell carcinomas usually invade the splenic flexure or the distal transverse or proximal descending colon,⁹⁶ whereas right-sided renal cell carcinomas invade the descending duodenum. Colonic invasion by renal cell carcinoma is usually

manifested on barium enema by bulky intraluminal masses, without signs of obstruction.⁹⁶

DIRECT INVASION FROM NONCONTIGUOUS PRIMARY TUMORS

Malignancies may spread in the subperitoneal space or by lymphatic permeation.⁹⁶ Examples of this mode of dissemination include colonic carcinoma invading the stomach via the gastocolic ligament,¹⁰⁷ pancreatic carcinoma invading the transverse colon via the transverse mesocolon, gastric carcinoma invading the transverse colon via the gastocolic ligament,⁹⁶ and colonic carcinoma invading contiguous loops of small bowel or colon.¹⁰⁸ The gastocolic ligament (the proximal part of the greater omentum) is the anatomic bridge between the greater curvature of the stomach and superior border of the transverse colon (Fig. 60-15).¹⁰⁴ When gastric carcinoma spreads to the transverse colon via the gastocolic ligament, mass effect, fixation, and fold spiculation are initially seen along the superior border of the transverse colon, with sacculation of the uninvolved inferior border. Rarely, the involved colon may have a cobblestone-like appearance indistinguishable from that of Crohn's disease. The major considerations in the differential diagnosis include gastric carcinoma invading the transverse colon and an omental cake from peritoneal metastasis secondarily invading the transverse colon.¹⁰⁹

The transverse mesocolon courses from the retroperitoneum overlying the pancreas to the inferior border of the transverse colon.⁹⁷ Therefore, when pancreatic carcinoma invades

Figure 60-13 Rectal invasion by prostatic carcinoma. **A.** Frontal view of the rectum shows mass effect and spiculation predominantly along the right lateral wall of the rectum (short arrows) and pleating of the mucosa en face (long arrows). Invasion of the mucosa and submucosa was confirmed on biopsy specimens of the right lateral rectal wall. **B.** Lateral view of the rectum shows mass effect along the anterior rectal wall and spiculation of the mucosal contour (straight arrows). Mild circumferential extension is seen distally (curved arrows). (From Rubesin SE, Levine MS, Bezzi M, et al: Rectal involvement by prostatic carcinoma: Radiographic findings. *AJR* 152:53-57, 1989.)

Figure 60-14 Direct colonic invasion by left ovarian carcinoma. Close-up view of an overhead radiograph from a double-contrast barium enema shows spiculation and mass effect along the inferior border of the sigmoid colon (open arrows) and pleating of the mucosa of the rectosigmoid junction en face (solid arrow).

the transverse colon via the transverse mesocolon, the initial radiographic changes occur on the inferior border of the transverse colon.⁹⁶ Despite these anatomic attachments, pancreatic carcinoma may occasionally spread to the superior border of the transverse colon (Fig. 60-16). Carcinoma of the pancreatic tail may extend along the phrenicocolic ligament to invade the medial border of the splenic flexure.⁹⁷

INTRAPERITONEAL SEEDING

The most common primary tumors that seed the peritoneal cavity are ovarian carcinoma in women and gastric, pancreatic, and colonic carcinomas in men. When appendiceal mucinous adenocarcinomas spread intraperitoneally, they result in a condition termed *pseudomyxoma peritonei*. Occasionally, lymph node metastases to the retroperitoneum or mesentery from breast carcinoma or other malignant tumors may secondarily seed the peritoneal cavity. Other tumors that spread intraperitoneally include carcinoma of the bladder, uterus, and cervix and hepatocellular carcinoma.

The peritoneal cavity is separated into various compartments by peritoneal reflections and mesenteries (Fig. 60-17).¹¹³ The transverse mesocolon divides the abdomen into the supramesocolic and inframesocolic spaces.^{110,111} The small bowel mesentery divides the inframesocolic space into small right

Figure 60-15 Sagittal line drawing of the abdomen. The proximal part of the greater omentum (gastrocolic ligament) bridges the greater curvature of the stomach with the anterosuperior border of the transverse colon. Thus, when gastric or omental processes directly invade the colon, the superior border of the transverse colon is involved first. The transverse mesocolon suspends the transverse colon from the retroperitoneum overlying the pancreas. (Adapted from Rubesin SE, Fishman EK: *Peritoneal metastasis*. In Fishman EK, Jones B [eds]: *Computed Tomography of the Gastrointestinal Tract*. New York, Churchill Livingstone, 1986.)

Figure 60-16 Pancreatic carcinoma invading the transverse colon. Overhead radiograph from a double-contrast barium enema shows extrinsic mass effect and spiculation along the superior border of the transverse colon (arrow). Contrast medium is present in the renal collecting systems from a prior intravenous urogram.

Figure 60-17 Directed flow of intraperitoneal fluid. The peritoneal reflections direct the flow of intraperitoneal fluid within the peritoneal cavity. Flow from the left inframesocolic space pools in the sigmoid mesentery along the superior border of the sigmoid colon and then courses into the pelvic cavity (pouch of Douglas in women, rectovesical space in men, and pararectal spaces). Flow in the right inframesocolic space courses down the ruffles of the small bowel mesentery into the right lower quadrant along distal small bowel loops and medial border of the cecum and then into the pelvic cavity from this region. Fluid from the pelvic cavity then courses up the right paracolic gutter to the right subhepatic space and right subdiaphragmatic space. Thus, the sites of pooling of ascitic fluid (superior border of the sigmoid colon, pouch of Douglas or rectovesical space, medial border of the cecum, mesenteric border of the distal small bowel, and right paracolic gutter) are the predominant sites for intraperitoneal seeding by tumor.

and large left regions.¹¹¹ The phrenicocolic ligament partially separates the left subphrenic space from the left paracolic gutter, extending from the splenic flexure of the colon to the peritoneum overlying the 11th rib.¹¹⁰ These peritoneal reflections direct the flow of intraperitoneal fluid, affecting the distribution and deposition of intraperitoneal-seeded infections and metastases. Directed flow results in characteristic sites of tumor deposition. As the most dependent portion of the peritoneal cavity in the supine and upright positions, the pouch of Douglas or rectovesical space is the most common site for intraperitoneal metastases (occurring in 56% of cases) (Fig. 60-18).¹¹⁰ Other sites include the right lower quadrant small bowel loops and medial border of the cecum (41%), superior border of the sigmoid colon (21%), lateral border of the ascending colon (the right paracolic gutter) (18%), and transverse colon.¹¹⁰

Radiographic Findings

Independent of the site of intraperitoneal-seeded metastases, the radiographic findings are similar. Initially, there is extrinsic mass effect along the side of the bowel wall bathed in peritoneal fluid. Direct invasion of the serosa or muscular layers of the bowel wall by tumor incites a desmoplastic reaction. On barium enema, this desmoplastic reaction is manifested in profile by spiculation of the luminal contour and en face by tethering and pleating of mucosal folds in a fixed, parallel, or angulated pattern.^{109,112} Angulation of bowel loops occurs predominantly in the sigmoid colon and small bowel. The major considerations in the differential diagnosis of serosal desmoplastic disease in the pouch of Douglas (or rectovesical space in men) include endometriosis, prostatic or cervical carcinoma invading the rectum, and an inflammatory process in the pouch of Douglas or rectovesical space such as a tubo-ovarian abscess or abscess caused by diverticulitis, appendicitis,

Figure 60-18 Intraperitoneal metastases from ovarian cancer invading the rectosigmoid junction. Left side-down decubitus radiograph from double-contrast barium enema shows mass effect (arrows) on the left anterolateral wall of the rectosigmoid junction. The contour is spiculated. The mucosa, although thrown into thick folds, is smooth.

or Crohn's disease. The clinical history, physical findings, and age of the patient usually allow differentiation of the various causes.

Cecal metastases are invariably accompanied by small bowel changes, including scalloping of the mesenteric border of right

lower quadrant ileal loops, fixation and angulation of loops, and spiculation of the luminal contour.¹⁰⁴

When peritoneal metastases involve the greater omentum, they may secondarily abut and invade the serosa of the transverse colon.¹¹³ These omental cakes initially involve the superior border of the transverse colon at the site of attachment of the greater omentum.¹⁰⁹ Mass effect may be seen along the superior border of the transverse colon on barium enema, with spiculation of the luminal contour and pleating and tethering of mucosal folds (Fig. 60-19). The major consideration in the differential diagnosis is gastric carcinoma invading the transverse colon via the gastocolic ligament. The clinical history and presence of metastases involving other portions of the colon should suggest the correct diagnosis.^{109,113} Inflammatory processes involving the gastocolic ligament, such as cholecystitis, pancreatitis, or diverticulitis, may produce identical radiographic findings.

EMBOLIC METASTASES

The most common primary tumors resulting in embolic metastases to the colon include malignant melanoma and breast and lung carcinoma. Carcinoma of the breast is the most common primary malignant tumor that spreads to the colon, but breast metastases to the colon are usually small lesions that cause no symptoms. More than 5% of those who die of metastatic breast carcinoma are found to have metastases to the colon at autopsy.¹¹⁴ These metastases may appear on barium enema as mural nodules, eccentric strictures, or irregular areas of circumferential narrowing, producing a linitis plastica appearance.⁹⁷ Hematogenous metastases may occasionally simulate Crohn's disease of the colon.

Metastases to the colon from carcinoma of the lung are usually small serosal deposits that cause no symptoms.⁹⁷ Occasionally, however, lung metastases cause GI bleeding or obstruction.¹¹⁵ These metastases may appear radiographically as ulcerated submucosal masses (target lesions), short eccentric segments of narrowing, or large mesenteric masses with secondary desmoplastic serosal changes.⁹⁷

Malignant melanoma involves the small intestine more frequently than it involves the colon. Metastatic melanoma is usually manifested on barium enemas by umbilicated or ulcerated submucosal masses or by bulky, polypoid intraluminal masses.

Figure 60-19 Omental cake from ovarian carcinomatosis invading the transverse colon. **A.** Spot image from a double-contrast barium enema shows spiculation of the colonic contour (arrows) and thin transverse stripes traversing the colon as a result of pleating of the mucosa. **B.** CT scan shows enlargement and increased attenuation of greater omentum caused by an omental cake (open arrows) along the anterior border of the transverse colon (T). A large amount of malignant ascites deviates the colon and small bowel loops medially. At surgery, intraperitoneal and greater omental metastases from ovarian carcinoma were found.

Polyposis Syndromes

ANGELA D. LEVY | CARINA L. BUTLER | JAMES L. BUCK

CHAPTER OUTLINE

Familial Adenomatous Polyposis Syndrome

Colonic Manifestations

Extracolonic Gastrointestinal Manifestations

Extraintestinal Manifestations

Hamartomatous Polyposis Syndromes

Peutz-Jeghers Syndrome

Multiple Hamartoma Syndrome (Cowden Disease)

Juvenile Polyposis

Cronkhite-Canada Syndrome

Bannayan-Riley-Ruvalcaba Syndrome

The polyposis syndromes are rare but fascinating conditions. A thorough knowledge of the clinical and radiographic manifestations of these syndromes and their complications is required to provide optimal care for affected individuals and their families.

Familial Adenomatous Polyposis Syndrome

Familial polyposis coli, attenuated familial adenomatous polyposis, and Gardner syndrome are varying expressions of the same disease. Most cases are caused by the presence of an abnormal tumor suppressor gene (the *APC* gene) located on the long arm of chromosome 5.¹ As a result, the term *familial adenomatous polyposis syndrome* (FAPS) is used to refer to the entire spectrum of this disease.

FAPS is a relatively rare condition, but it is the most common of the polyposis syndromes.² Males and females are equally affected. FAPS has an autosomal dominant pattern of inheritance when associated with the *APC* gene mutation. However, up to 30% of patients have no family history of polyposis, suggesting the presence of spontaneous mutations or an association with a different mutation.^{3,4} A family history of polyposis or colorectal cancer therefore is not required for the diagnosis of FAPS. Penetrance is generally thought to be in the range of 80% to 100%, although in one series it was calculated to be less than 60%.⁵ In most families, comparative DNA testing alone can determine whether a family member is carrying the abnormal *APC* gene.⁶

In 5% to 30% of patients with FAPS, however, no *APC* mutation can be identified by current genetic testing.⁴ A different gene (the *MUTYH* gene) has also been linked to *APC*-negative patients with FAPS.⁴ Interestingly, FAPS associated with the *MUTYH* gene is thought to be inherited in an autosomal recessive fashion. The acronym MAP is used for *MUTYH*-associated polyposis. Synonyms include colorectal

adenomatous polyposis, autosomal recessive, multiple colorectal adenomas, autosomal recessive, and *MHY*-associated polyposis. Patients with the *MUTYH* mutation appear to have a milder form of the disease than those with the *APC* mutation.^{7,8} Patients with MAP have fewer polyps (10 to a few hundred, and occasionally few or none) compared to patients with FAP and an older mean age of 50 years at presentation.⁹ Extracolonic manifestations similar to those of FAP may occur, but with decreased incidence.

COLONIC MANIFESTATIONS

As the name implies, FAPS is predominantly associated with the development of adenomas. In the colon, where the polyposis is most severe, the polyps are usually tubular or tubulovillous adenomas. Occasionally, villous adenomas are also seen. The polyps usually appear at or near puberty and, eventually, an average of about 1000 colonic adenomas will develop.¹⁰ The adenomas of FAPS are usually small (80% are <5 mm in diameter) and sessile. The polyps involve all portions of the colon but may first appear distally. Rectal sparing occasionally may be seen.

A milder phenotype of FAPS, known as attenuated familial adenomatous polyposis syndrome (AFAPS), has recently been described. These patients generally present with 100 or fewer colonic adenomas.^{11,12} The adenomas tend to be located more proximally than those in classic FAPS, so sigmoidoscopy alone is inadequate for evaluating these patients.^{13,14} Colonic carcinoma also develops at an older age, with an average age of 55 years in patients with AFAPS versus an average age of 40 years in patients with classic FAPS. There is no current consensus on the diagnostic criteria for AFAPS, but it should be considered in a patient with a personal history of colorectal cancer before 60 years of age and a family history of multiple adenomatous polyps and in those with more than 10 but less than 100 polyps.¹⁵

The most common clinical symptoms encountered in FAPS are rectal bleeding and diarrhea, which occur in more than 75% of patients. Abdominal pain, anemia, and mucous discharge are less frequently noted.^{16,17} However, many patients with FAPS are asymptomatic. Regardless of symptoms, colonic carcinomas develop in almost every untreated patient and at a much younger age than in the general population.³ The average age of colon cancer in untreated patients is 39 years.^{17,18} Thus, DNA testing or serial colonic examinations after 10 years of age are recommended for other family members at risk for the disease.¹³

Total colectomy with mucosal proctectomy and ileoanal anastomosis is the procedure of choice for treatment because it eliminates all colonic and rectal mucosa.¹⁹ Surgical intervention should be performed by the late teenage years.¹⁷ After surgery, continued surveillance is necessary because any surgical procedure that restores intestinal continuity bears a continued risk of malignancy in the surgical remnant. For patients who have

undergone ileorectal anastomoses prior to current surgical recommendations for total colectomy with mucosal proctectomy and ileoanal anastomosis, completion surgery should be considered because recurring adenomas in the remaining rectal mucosa cannot be adequately controlled endoscopically.

The radiographic appearance of the colon in FAPS varies. Typically, innumerable small or moderate-sized sessile filling defects carpet the entire colon (Fig. 61-1A). Larger pedunculated polyps are less common. In some younger patients, however, the polyps may be more widely scattered (Fig. 61-1B). Correlation with colectomy specimens has shown that barium enemas markedly underestimate the number of polyps, especially in young patients, whose polyps are often smaller than 3 mm in diameter.¹⁸ Unfortunately, carcinomas still develop because of inadequate screening of family members at risk for

the disease. Carcinoma may be manifested by a dominant polyp (Fig. 61-2), saddle lesion, or advanced annular lesion (Fig. 61-3). As in the general population, carcinomas are usually found in the left side of the colon.

EXTRACOLONIC GASTROINTESTINAL MANIFESTATIONS

Extracolonic gastrointestinal (GI) manifestations of FAPS are well recognized.²⁰⁻²⁸ Fundic gland polyps are the most common gastric manifestation of FAPS in Western countries, occurring in up to 84% of patients.^{29,30} In FAPS, both genders are equally involved, whereas in the absence of FAPS, fundic gland polyps are more common in females.^{31,32} The polyps are frequently discovered in asymptomatic patients at an average age of 25 to

Figure 61-1 Various appearances of colonic involvement by familial adenomatous polyposis syndrome. **A.** In a 10-year-old boy, a double-contrast barium enema demonstrates innumerable small polyps in the colon, particularly carpeting the rectosigmoid region. **B.** In a 17-year-old girl, a double-contrast barium enema shows scattered, small to moderate-sized polyps (arrows) in the sigmoid colon.

Figure 61-2 Colonic carcinoma in a 30-year-old man who presented with abdominal pain. **A, B.** Intravenous and oral contrast-enhanced CT shows liver metastases (arrowheads in **A**) and colocolic intussusception in the transverse colon. The lead point is a polypoid mass (arrow in **B**). **C.** Photograph of the resected colon shows a large polypoid adenocarcinoma and numerous small polyps.

Figure 61-3 Colonic carcinoma in familial adenomatous polyposis syndrome. An annular lesion is present in the sigmoid colon (arrow). Scattered small polyps are also present.

30 years and are almost invariably multiple, appearing as small sessile lesions ranging from 1 to 5 mm in diameter.³³ They are almost always confined to the fundus and body of the stomach. They are characteristically small (5–10 mm), smooth, sessile nodules protruding into the gastric lumen. There may be few or hundreds, which carpet the gastric fundus. On subsequent examinations, the polyps may progress, remain stable, or even resolve.^{34,35} These polyps have little tendency for malignant transformation, although gastric cancer has occasionally been reported in patients with preexisting fundic gland polyps.³²

Tubular and villous adenomas are also found in the stomach in patients with FAPS. In Japan, the incidence of gastric adenomas in FAPS ranges from 40% to 50%, whereas in Europe and North America, a lower incidence is reported.^{24,29} The higher incidence of adenomas associated with FAPS in Japan may be related to the higher frequency of adenomas and adenocarcinomas in the general population of that country.³⁷ Gastric adenomas are typically sessile polyps, ranging from 5 to 10 mm in diameter, and are multiple in over 50% of reported cases.³⁵ The adenomas are usually located in the distal stomach.³⁵ Unlike fundic gland polyps, gastric adenomas are premalignant lesions, so that periodic surveillance of the stomach is required.

The duodenum is the second most common site of GI disease in FAPS. Endoscopic examinations of asymptomatic patients in Japan have revealed tubular adenomas in more than 90% of cases.^{36–38} Other screening studies from Western countries have revealed adenomas in 47% to 72% of cases.^{39–41} The adenomas range from microscopic to 2 cm in diameter, with most being 5 mm or less. The polyps are usually found in the second portion of the duodenum, clustered around the papilla.³⁹

This differs from the typically bulbar distribution of adenomas in patients without FAPS.⁴⁰ Villous adenomas are also commonly found and, as in patients without FAPS, they tend to be located in the periampullary region of the duodenum. Villous adenomas are typically large and are even more likely to undergo malignant degeneration. It has been estimated that the lifetime incidence of periampullary carcinoma is as high as 12%, and that it is now the leading cause of cancer deaths in patients who have had a colectomy. It is therefore advocated that surveillance of the upper GI tract be performed in asymptomatic patients with FAPS beginning at 25 years of age.¹³

Adenomas in the jejunum and ileum have been identified in most patients in Japan who have undergone intraoperative small bowel endoscopy.³⁹ Small bowel endoscopy performed through a cutaneous ileostomy or ileoproctostomy has also revealed adenomas in approximately 20% of FAPS patients in Western countries.³⁶ As in the duodenum, these premalignant lesions are typically small and numerous. Although several cases of adenocarcinoma of the jejunum or ileum have been reported—coexisting adenomas have been found in all of these cases—the need for routine screening of the small bowel beyond the duodenum has not been established.⁴¹ Ileal lymphoid hyperplasia occurs more frequently in patients with FAPS than in the general population. The gross appearance of these lesions is similar to that of adenomas.⁴¹ However, lymphoid hyperplasia has no apparent clinical significance in these patients.

Biliary polyps are often found in patients with FAPS studied by endoscopic retrograde cholangiopancreatography.²⁶ Not surprisingly, cholangiocarcinoma and gallbladder carcinoma have also been reported in FAPS.^{42–47} Several cases of pancreatic carcinoma have been reported, and there is an increased incidence of pancreatitis in these patients.⁴⁹

EXTRAINTESTINAL MANIFESTATIONS

It was not until the 1950s that the extraintestinal manifestations of FAPS were well established. Gardner and Richards initially described a family of patients with adenomatous polyps of the colon, sebaceous cysts, and osteomas.^{48–50} Later, fibrous tumors and dental abnormalities were added to the list of lesions included in what was subsequently called *Gardner syndrome*.⁵¹ Numerous reports have subsequently confirmed the occurrence of these and other extraintestinal manifestations that have a tendency to appear in certain kindred affected by FAPS. The location of the defect in the *APC* gene and other intracellular factors appear to determine whether these manifestations are likely to appear.^{52,53} It is unusual to see all manifestations in the same patient.⁵⁴

Epidermoid (sebaceous) cysts are the skin lesions usually encountered in patients with FAPS. The cysts tend to be located on the face and scalp rather than on the back, as in the general population.⁴⁸ They are uncommon before puberty, but the presence of these cysts often precedes the recognition of colonic polyps. Otherwise, they have no clinical significance. Lipomas and small fibrous tumors of the skin are also found in FAPS.⁴⁸

Osteomas are another well-known manifestation of FAPS. Like epidermoid cysts, osteomas are usually unimportant unless they cause symptoms because of mass effect. In FAPS patients, these dense cortical lesions are usually found in the angle of the mandible, sinuses, and outer table of the skull (Fig. 61-4).^{55–60} Other flat bones and long bones may be involved. Bone islands are also quite common in the maxilla and mandible and may

Figure 61-4 Multiple osteomas in a 23-year-old man with familial adenomatous polyposis syndrome. Lateral radiograph of the face and skull demonstrates two dense bony lesions (white arrows) arising from the mandible. A subtle lesion (black arrow) is also seen in the frontal bone.

be seen in other flat bones as well.⁵⁸⁻⁶⁰ In one series, localized or diffuse cortical thickening of the long bones was the most commonly identified bone abnormality in FAPS.⁵⁵ Dental abnormalities, particularly unerupted teeth, supernumerary teeth, dentigerous cysts, and odontomas, are also common.⁵⁹

Fibrous proliferation is a less common but more important feature of FAPS. An increased incidence of postoperative peritoneal adhesions occurs in FAPS, and retroperitoneal fibrosis has also been reported.⁶¹⁻⁶³ Usually, these patients develop fibrous tumors (particularly desmoid tumors of the abdominal wall) and mesenteric fibromatosis (Fig. 61-5). Histologically, desmoids are benign lesions but are nonencapsulated. In FAPS, these tumors often develop postoperatively, occurring within abdominal incisions, the peritoneal cavity, or the retroperitoneum.⁶² They usually develop in women of childbearing age and may grow rapidly or may first appear during pregnancy or after exposure to oral contraceptives.⁶² These tumors may recur locally after resection, and invasion of bowel is common. Death may result from intestinal or vascular obstruction, particularly when the lesions are located within the peritoneal cavity. With improvements in computed tomography (CT), more subtle, diffuse soft tissue infiltration of the mesentery can be identified, but this appearance is less likely to be associated with symptoms than is an actual mesenteric mass.⁶²

Congenital pigmented lesions of the retina are common in patients with FAPS; the prevalence of these lesions may be higher than 90%.⁶⁴⁻⁶⁸ Although similar lesions are occasionally found in the general population, the presence of large,

Figure 61-5 Mesenteric fibromatosis in a 25-year-old woman with familial adenomatous polyposis syndrome. She is status post total colectomy with ileoanal anastomosis. Intravenous and oral contrast-enhanced CT shows a large heterogeneous mass (arrow) arising in the small bowel mesentery adjacent to the ileoanal anastomosis.

multifocal, or bilateral pigmented lesions on fundoscopic examination is a strong indicator of FAPS. These lesions may occur before the development of colonic polyposis, serving as a marker for FAPS, but the absence of these lesions does not exclude FAPS.⁶⁸

Much has been learned about the association between colonic carcinoma and central nervous system malignancies, a condition traditionally known as Turcot syndrome.⁶⁹⁻⁷² Evidence suggests that many, if not most, of these cases (including those in the family first described by Turcot) are actually related to the hereditary nonpolyposis colon cancer syndrome (HNPCCS) and do not have abnormalities of the *APC* gene.⁷⁰ Nevertheless, central nervous system tumors are important extraintestinal manifestations of FAPS. There is clearly an increased incidence of medulloblastomas. There have also been case reports of benign intracranial tumors associated with FAPS, including intracranial epidermoid cysts and meningiomas.⁷¹ Glial tumors such as ependymomas and astrocytomas also occur in FAPS.⁷¹ However, many cases of glioblastoma multiforme associated with colonic adenomas or carcinomas that were reported in the past were probably related to HNPCCS.

The prevalence of thyroid carcinoma in FAPS has been calculated to be 160 times greater than that in the general population. Almost all reported cases are papillary, and they are frequently multifocal.⁷³⁻⁷⁵ In most series, affected individuals are girls or young women, and the thyroid carcinoma is usually detected before colonic polyposis becomes apparent. FAPS therefore should be suspected in young women with papillary carcinoma of the thyroid.⁷⁵ In one series, however, there was no female predominance in patients with thyroid carcinoma and FAPS.⁷⁴ Other endocrine tumors, including multiple endocrine neoplasia type 2, carcinoid tumors, and adrenocortical adenomas and carcinomas, have also been reported in patients with FAPS.⁷⁶⁻⁸⁰

Several tumors of the pancreas and liver have been reported in FAPS, including pancreatic carcinoma.⁸¹ Solid and papillary epithelial neoplasm, neuroendocrine tumors, and intraductal

papillary mucinous tumors of the pancreas have also been reported. Because of the rarity of these tumors, screening of FAPS patients for pancreatic lesions does not appear to be warranted. Hepatoblastomas have also been reported with increased frequency in the children of patients with FAPS.⁸²

Hamartomatous Polyposis Syndromes

The other polyposis syndromes, which occur less frequently than FAPS, include Peutz-Jeghers syndrome (PJS), multiple hamartoma syndrome (MHS), juvenile polyposis (JP), Cronkhite-Canada syndrome (CCS), and Bannayan-Riley-Ruvalcaba syndrome (BRRS). These conditions are collectively known as the hamartomatous polyposis syndromes.⁸²⁻⁸⁵ The term *hamartoma* implies a non-neoplastic tumor composed of normal tissue elements. Hamartomatous polyps may coexist with adenomatous polyps, explaining the association of alimentary tract adenocarcinoma with most of these syndromes, although they account for less than 1% of all colorectal carcinomas in North America.⁸⁶

PEUTZ-JEGHERS SYNDROME

PJS is an inherited condition characterized by a unique type of GI hamartoma, mucocutaneous pigmentation, neoplasms outside the alimentary tract, and an increased risk for GI carcinoma. PJS has an autosomal dominant pattern of inheritance and affects both genders equally. The only gene associated with PJS is a tumor suppressor gene, *STK11*, previously known as *LKB1* gene, located on chromosome 19.⁸⁵⁻⁸⁸ There are, however, a substantial number of PJS patients in whom there is no linkage to chromosome 19, suggesting that other genes also play a role in the development of this syndrome.

The characteristic feature of the PJS hamartoma is a smooth muscle core arising from the muscularis mucosae and extending into the polyp, much like the trunk and branches of a tree. The mucosa covering the polyp is similar to that normally found in the portion of the gut in which the polyp arises. Some PJS polyps may cause displacement of the epithelial elements within the submucosa, muscularis propria, and subserosa; this finding should not be mistaken for an invasive mucinous adenocarcinoma.⁸⁴

Mucocutaneous pigmentation is one of the most characteristic features of PJS. Brown or bluish-black macules usually occur on the lips and buccal mucosa (Fig. 61-6) and, less commonly, on the eyelids and dorsal surfaces of the fingers and soles of the feet. The pigmentation is rarely present at birth, usually appearing after the first or second year of life. The skin and lip pigmentation fades gradually in adulthood, whereas the macules on the buccal mucosa remain unchanged.^{83,86}

Most patients have recurrent episodes of abdominal pain related to small bowel intussusceptions caused by the hamartomatous polyps. These intussusceptions usually resolve spontaneously. However, persistent intussusceptions may cause small bowel obstruction, necessitating surgical intervention. Less frequently, patients may have rectal bleeding or melena. Life-threatening GI hemorrhage is extremely uncommon.⁸⁶

Patients with PJS are at increased risk for developing adenocarcinoma of the GI tract. Most of these carcinomas are located in the colon, followed in decreasing order of frequency, by the stomach, duodenum, and esophagus.⁸⁶ Although the exact prevalence of GI carcinoma is unclear, studies suggest that at least

Figure 61-6 Classic mucocutaneous pigmentation of Peutz-Jeghers syndrome. Bluish black macules are seen on the lips and buccal mucosa.

10% of patients with PJS develop GI cancer^{88,89} and that females with PJS are more likely to develop these tumors.^{86,90} It is uncertain whether carcinoma in PJS develops from malignant transformation of a hamartomatous polyp, from a coexisting adenomatous polyp, or de novo. However, cases of dysplasia and carcinoma occurring within a PJS hamartoma are well documented.⁹¹⁻⁹⁸

Patients with PJS are also at increased risk for developing extraintestinal malignancies, which have a reported prevalence of 10% to 30%. The most commonly implicated tumors include carcinoma of the pancreas, breast, and ovary.⁹⁹⁻¹⁰³ Pancreatic cancers in PJS have a tendency to develop at an unusually early age, with the risk estimated to be 200 times greater than that in the general population.^{99,101-105} Breast cancer tends to occur in young women, is usually ductal, and is commonly bilateral.¹⁰⁶ The risk for breast cancer in patients with PJS is similar in magnitude to that in patients with hereditary breast cancer (*BRCA1* and *BRCA2*).¹⁰⁷

Rare neoplasms of the reproductive tract may also occur in patients with PJS. Adenoma malignum is a uterine cervix cancer with a relatively benign histologic appearance but an aggressive biologic behavior.¹⁰⁸⁻¹¹¹ A benign ovarian tumor, designated as sex cord tumor with annular tubules (SCTAT), also commonly occurs in women with PJS.¹¹¹⁻¹¹³ These tumors are often bilateral, small or microscopic, and calcified, whereas in patients with SCTAT without PJS, the tumors are usually larger and unilateral.¹¹⁰ These benign ovarian tumors are capable of producing both estrogen and progesterone. In fact, hyperestrogenism may contribute to the increased incidence of breast carcinoma in patients with PJS. More common benign and malignant ovarian neoplasms also occur. Sertoli cell tumors of the testes have occasionally been reported in males with PJS. Like SCTAT, these tumors are benign, microscopic, and often bilateral. They may also produce estrogen, leading to gynecomastia.¹¹⁵ Other neoplasms reported less frequently in patients with PJS include benign and malignant tumors of the thyroid gland, gallbladder, ureter, urinary bladder, bronchus, and nasal cavity.^{99,101,114-118}

PJS hamartomas are found predominantly in the jejunum and ileum, followed by the duodenum, colon, and stomach (Figs. 61-7 and 61-8).¹¹⁹ Individual polyps vary in size and may be pedunculated or sessile. Pedunculated polyps are usually

Figure 61-7 Fluoroscopic features of Peutz-Jeghers syndrome. **A.** Spot radiograph from a double-contrast upper gastrointestinal series in a patient with Peutz-Jeghers syndrome shows a multilobulated polyp (arrow) on a stalk (arrowhead) in the stomach. **B.** Radiograph from a small bowel series in a different patient shows a lobular filling defect (arrowhead) in the jejunum from a hamartomatous polyp and intussusception (arrows).

Figure 61-8 Peutz-Jeghers syndrome in a 22-year-old man who presented with acute abdominal pain, nausea, and vomiting. **A-D.** Intravenous and oral contrast-enhanced CT shows multiple hamartomas polyps throughout the gastrointestinal tract. Polyps are present in the stomach and colon (arrows in **A** and **D**). Two small bowel intussusceptions are present (arrows in **B** and **C**).

located in the small bowel or colon, whereas sessile polyps are more common in the stomach.¹²⁰ Larger hamartomas often have a lobulated surface (see Fig. 61-7A). It is more common for PJS polyps to occur in clusters than for the lesions to carpet the bowel.⁸⁸ A solitary hamartoma involving one segment of the GI tract may occur but is uncommon. Intussusception caused by small bowel hamartomas is an important radiologic feature of PJS. Transient intussusceptions may occasionally be observed on barium studies, ultrasonograms, and CT scans.¹¹⁸

A combination of radiologic and endoscopic studies should be used to diagnose these polyps. Upper endoscopy and screening of the small bowel with capsule endoscopy, magnetic resonance (MR) enterography, or CT enterography is recommended for surveillance beginning at 8 years of age or when symptoms occur.¹²² Colonoscopy should also begin at age 8 and repeated every 3 years.¹²² Ultrasonography is particularly useful for detecting ovarian and testicular tumors. The role of screening mammography for young women (25-35 years of age) with

PJS remains controversial. Screening with breast MR imaging (MRI) in addition to self-examination has been recommended.¹¹⁹ Cross-sectional imaging studies may be helpful for the diagnosis of extraintestinal abnormalities.

When a preoperative diagnosis of PJS is made, these patients can benefit from intraoperative endoscopic removal of small bowel polyps, a procedure that reduces the risk of adenocarcinoma and further intussusceptions. This form of treatment is preferable to small bowel resection because some patients with PJS develop short bowel syndrome from multiple enterectomies.¹²²

MULTIPLE HAMARTOMA SYNDROME (COWDEN DISEASE)

MHS is a genodermatosis characterized by hamartomas and neoplasms of ectodermal, mesodermal, and endodermal origin, affecting multiple organs and organ systems.¹²³⁻¹²⁷ The prevalence of MHS is 1 per 200,000. Patients usually present in their late teens or early 20s, with almost all patients presenting by their late 30s.¹²⁸ The most consistent clinical features are mucocutaneous lesions associated with thyroid gland abnormalities, breast carcinoma, hamartomatous polyposis of the GI tract, and abnormalities of the central nervous system. This syndrome has an autosomal dominant pattern of inheritance. As many as 80% of patients with MHS have a mutation in the tumor suppressor gene *PTEN* located on the long arm of chromosome 10.¹²⁹ As a result, patients with MHS and *PTEN* mutation are classified as part of the *PTEN* hamartoma syndrome, which also includes patients with *PTEN* mutations and BRRS, *PTEN*-related Proteus syndrome, and Proteus-like syndrome.¹²⁹

Mucocutaneous lesions are present in almost all patients with MHS and are considered the hallmark of the disease. Facial trichilemmomas are pathognomonic of MHS and can develop before the internal manifestations of this condition. Keratotic papules around the mouth and nose, labial and oral mucosal papillomatoses, acral keratoses, and multiple sclerotic fibromas are the most characteristic lesions, serving as external markers for the syndrome.¹³⁰⁻¹³⁸ These benign mucocutaneous lesions almost always develop early in the disease (usually in the third decade of life) before the neoplastic manifestations have developed.¹³⁹ Recognition of these features is therefore essential for the early diagnosis of MHS and initiation of screening programs for associated neoplasia.

Thyroid disease is the most frequent extracutaneous abnormality, occurring in about 65% of patients with MHS. Goiters and adenomas are the most common lesions, and men and women are affected equally.^{123,131} Thyroid carcinoma has been reported in about 10% of patients, with the most common subtypes being follicular and papillary carcinoma. Almost all cases of thyroid carcinoma have been reported in women.^{126,134}

About 70% of women with MHS have breast lesions. Fibrocystic disease is the most common finding, occurring in at least 50% of patients.^{126,137,140,141} Carcinoma of the breast (often bilateral ductal cancer) is the most common malignant tumor in MHS, occurring in 25% to 50% of patients.¹³⁷ The age at onset is 38 to 46 years, which is earlier than expected for the general population. Breast screening with self-examination, MRI, and possibly mammography, as in patients with PJS, should be encouraged in young women with MHS.

Multiple central nervous system abnormalities have also been described in patients with MHS. Lhermitte-Duclos disease (dysplastic gangliocytomas of the cerebellar cortex) is readily diagnosed by MRI of the brain and is now considered one of the major criteria for the diagnosis of MHS.¹⁴⁰⁻¹⁴³ After MHS or Lhermitte-Duclos disease has been diagnosed, careful evaluation of the patient for the other entity is therefore crucial.¹⁴⁸ Meningiomas and vascular malformations, including venous angiomas and cavernous angiomas, have also been found to occur in patients with MHS.^{144,145}

Many patients with MHS have facial or skeletal abnormalities. Macrocephaly, with a high broad forehead, is one of the most characteristic features.¹⁴⁵ Progressive macrocephaly may be accompanied by a delay in psychomotor development.¹⁴⁵

Genitourinary lesions are frequent and include uterine leiomyomas, endometrial and cervical carcinomas, and transitional cell carcinomas of the renal pelvis and urinary bladder.¹³⁹ Renal cell carcinomas have also been reported.

Polyps of the GI tract occur in 70% to 85% of patients with MHS.¹⁴⁶⁻¹⁵² They occur in all segments of the GI tract with variable reported histology, including hamartomas, hyperplastic polyps, and adenomatous polyps, followed less frequently by lipomas, ganglioneuromas, and inflammatory fibroid polyps. When present, hyperplastic polyps are usually located in the stomach, and adenomatous polyps are usually located in the stomach or colon.^{150,151} The hamartomas in MHS differ histologically from the hamartomas in PJS. They are usually sessile and smaller, with less exophytic and arborizing proliferation of the muscularis mucosae. Hamartomatous polyps are the most commonly described polyps in MHS and are the predominant lesions in the rectosigmoid colon.^{151,156} Although hamartomas occur in the esophagus, glycogenic acanthosis appears to be a more consistent finding in the esophagus and is considered by some to be another characteristic feature of MHS (Fig. 61-9).¹⁵²

The GI polyps of MHS usually appear radiographically as multiple small, sessile lesions with a segmental or diffuse distribution. They are usually located in the rectosigmoid colon followed, in decreasing order of frequency, by the stomach, duodenum, small bowel, and esophagus.^{151,152}

In most patients, GI polyps cause no symptoms and are usually found incidentally or during screening for MHS. Rare cases of colon and gastric carcinoma have been described in MHS, but an increased risk of developing these malignancies in patients with MHS has not been established.^{150,151,153}

JUVENILE POLYPOSIS

Although an isolated juvenile polyp is the most common tumor of the colon in children, JP is a rare disease. The age at onset is variable, but most patients present during the second decade of life.^{154-159,161} The criteria for establishing a diagnosis of JP include the following: (1) more than five juvenile polyps in the colon or rectum; (2) juvenile polyps throughout the GI tract; and/or (3) any number of juvenile polyps in a patient with a family history of juvenile polyps.¹⁵⁸ Affected individuals may present with bleeding, obstruction, and intussusception, but many patients are asymptomatic.

The genetics are not precisely defined, but JP appears to have an autosomal dominant pattern of inheritance.¹⁵⁸ About 25% of newly diagnosed cases of JP are sporadic; the remaining 75% of patients have a family history of JP. Two genes have been

Figure 61-9 Glycogen acanthosis in multiple hamartoma syndrome. **A.** Multiple lucent plaque-like filling defects are present in the esophagus on a double-contrast esophagram. **B.** Endoscopic photograph shows characteristic white plaques with normal surrounding mucosa.

implicated in the development of JP. One gene is located on chromosome 18 (*SMAD4*) and the other on chromosome 10 (*BMPRIA*).¹⁵⁸ Approximately 20% of patients with JP have mutations in *BMPRIA* and 20% have mutations in *SMAD4*.¹⁵⁸ Various congenital anomalies, including hydrocephalus and pulmonary venous malformations, occur in 25% of nonfamilial cases of JPS but are rare in patients with the familial form of the disease.^{159,160}

Patients with JP are at increased risk for developing malignant tumors of the colon, stomach, small intestine, and pancreas.¹⁶¹⁻¹⁶⁸ Evidence indicates that the risk of colon cancer is 17% to 22% by 35 years of age and as high as 68% by 60 years of age. In patients with gastric polyps, the incidence of gastric carcinoma is more than 20%.^{158,162} Precancerous dysplasia in juvenile polyps has been well documented and suggests that carcinoma may arise in such lesions. Current screening recommendations for patients with JP include colonoscopy every 1 to 2 years beginning at 15 years of age and upper endoscopy beginning at 25 years of age.¹⁵⁸ Investigators have found that family members of patients with JP may also be at risk for developing malignant tumors of the GI tract, so the families of these patients should also be evaluated carefully.¹⁶⁵

In the colon, the polyps vary in size but, as in patients with isolated juvenile polyps, they tend to be large lesions with a diameter of 1 cm or more. These polyps can be sessile or pedunculated. When the polyps are distributed throughout the GI, they are still more likely to be clustered than to carpet the mucosa. In decreasing order of frequency, the polyps in JP occur in the colon, stomach, small bowel, and duodenum. Gastric polyps in JP are predominantly located in the gastric antrum (Fig. 61-10).¹⁶⁹⁻¹⁷⁵

JP of infancy is a severe disease.¹⁷⁶⁻¹⁸⁰ Most patients present in the first 2 years of life with a devastating mucoid or bloody diarrhea. There is usually no family history of JP. Anemia, hypoproteinemia, and repeated episodes of bronchopulmonary infection and small bowel intussusception result in early death

for most patients. Ectodermal changes resembling those of adult Cronkhite-Canada syndrome and congenital anomalies, including clubbing of the fingers, macrocephaly, and arachnoid cysts, have been reported in a small number of patients.¹⁸⁰ Juvenile polyps vary in size and are distributed throughout the GI tract, except for the esophagus. The small bowel and colon are most severely affected.¹⁸¹

CRONKHITE-CANADA SYNDROME

Unlike most of the other polyposis syndromes, CCS is not familial and occurs in older adults.¹⁸²⁻¹⁸⁸ The average age at onset is 60 years, with an age distribution of 31 to 76 years. (A condition known as Cronkhite-Canada syndrome of infancy is probably the same disease as infantile juvenile polyposis.) Mental and physical stress has been suggested as an important factor in the development of this disorder.¹⁸⁵

The histologic appearance of the GI polyps was not characterized in the first reported cases, but it is generally thought that the lesions of CCS are inflammatory polyps.¹⁸⁸ Adenomatous, hyperplastic, and hamartomatous polyps have also been reported in smaller numbers in patients.¹⁸⁸⁻¹⁹⁰ Colon cancer has been reported in about 12% of the 387 documented cases of CCS to date.¹⁹⁰

Patients with CCS typically present with abdominal pain, anorexia, a severe protein-losing diarrhea, malabsorption, and weight loss. This severe diarrhea causes electrolyte disturbances, anemia, and hypoproteinemia. Ectodermal abnormalities of the skin, hair, and nails generally follow the onset of GI symptoms. Hair loss involving the scalp or body occurs abruptly. Brown macules develop on the palmar and plantar skin surfaces. Dys-trophic changes in the nails may lead to complete nail loss (Fig. 61-11). Rarely, the ectodermal manifestations precede the onset of GI disease.^{189,191} The ectodermal changes and even the GI polyps may regress when clinical remission occurs.^{187,190,191} The prognosis is usually poor, with a mortality rate of more than

Figure 61-10 Juvenile polyposis in a 52-year-old man presenting with hematemesis. He had a family history of juvenile polyposis and a history of colonic juvenile polyp resection.
A. Radiograph from an upper gastrointestinal series shows innumerable filling defects in a distended stomach.
B. Intravenous contrast-enhanced CT shows innumerable low-attenuation polyps nearly filling the stomach.

Figure 61-11 Radiographic and clinical features of Cronkhite-Canada syndrome.
A. In a 34-year-old woman, a double-contrast study of the stomach shows carpeting of the mucosa with hamartomatous polyps superimposed on enlarged rugal folds.
B. Dystrophic nail changes are seen in a different patient with Cronkhite-Canada syndrome.

50%. However, evidence has suggested a more favorable prognosis after intense therapy with corticosteroids and nutritional support.^{191,192}

Polyyps in CCS usually appear on barium studies as small, sessile or, less commonly, pedunculated lesions. They are almost always distributed throughout the stomach, small bowel, and colon.¹⁹³ Definite esophageal involvement has not been reported. In the stomach, small to moderate-sized polyps carpet the mucosal surface, usually superimposed on thickened rugal folds (see Fig. 61-11). The small bowel may contain multiple small polyps from the duodenum to the terminal ileum. The colon and rectum may also be diffusely involved, but carpeting of the mucosa is not as extensive as that in the stomach.¹⁹³

BANNAYAN-RILEY-RUVALCABA SYNDROME

Because of overlapping clinical features, three syndromes—Riley-Smith syndrome, Bannayan-Zonana syndrome, and Ruvalcaba-Myhre-Smith syndrome—have been combined into

a single entity, the Bannayan-Riley-Ruvalcaba syndrome (BRRS).^{194,195} This syndrome has an autosomal dominant pattern of inheritance.^{194,195} A *PTEN* gene mutation is present in 50% to 60% of patients with BRRS, the same gene associated with MHS.¹³⁸ Some authors now believe that BRRS and MHS may be the same syndrome, because there is overlap in the genetic and clinical manifestations of these diseases.⁸³ Also, families have been reported in which some members had MHS and others had BRRS.¹⁴²

The most common clinical features of BRRS include macrocephaly and multiple subcutaneous and visceral lipomas and hemangiomas. About 50% of patients have delayed psychomotor development, hypotonia, and mild to severe mental deficiency. Male patients may have pigmented spotting of the penis.

Hamartomatous intestinal polyps are present in about 45% of patients with BRRS.¹⁹⁴ They are usually located in the distal ileum and colon but can be found throughout the GI tract.^{83,195-198} An increased risk of GI malignancy has not been described in these patients.

Urticaria
Colitis Cystica Profunda
Diarrhea

Colonic Obstruction

Mechanical large bowel obstruction is four to five times less common than small bowel obstruction and differs significantly in terms of cause (Table 62-1), pathophysiology, therapy, and prognosis.¹⁻⁴ Colon obstruction is most often the result of a neoplasm (Table 62-2), whereas most small bowel obstructions are caused by adhesions.^{5,6} A number of extracolonic disease processes, including gynecologic diseases, can secondarily involve the large bowel, leading to obstruction or formation of strictures and fistulas.⁷

PATHOPHYSIOLOGY

When colonic obstruction is caused by diverticulitis or cancer, symptoms are usually subacute or chronic. Swallowed air proximal to the obstruction causes dilation, but third spacing of fluid in the gut lumen characteristic of small bowel obstruction is not seen. Strangulation rarely occurs, except in occasional

cases of volvulus.⁸ Colonic response to the mechanical obstruction depends on the competency of the ileocecal valve (Fig. 62-1). The small bowel serves to decompress the colon when the valve is incompetent. A closed loop obstruction develops when the valve is competent because the colon cannot decompress.

The cecum has the largest diameter of the colon, and therefore its wall develops the highest tension, according to Laplace's law (wall tension = intraluminal pressure \times radius). The increased pressure may cause separation of the muscle fibers, leading to cecal diastatic perforation. Dissection of air into the wall results in pneumatosis, which may precede frank perforation.^{9,10} The risk of perforation increases when the cecum reaches a diameter of 9 to 12 cm.¹¹ The duration and rapidity of onset of the distention are also important.^{12,13} The intraluminal pressure needed to produce perforation is between 20 and 55 mm Hg.¹⁴ Ischemia and bacterial overgrowth also play a role in cecal perforation, and the systemic effects seen with strangulating obstruction.^{15,16}

TABLE 62-1 Causes of Mechanical Large Bowel Obstruction

Intrinsic Defects	Extrinsic Defects
Neoplasms	Volvulus
Benign	Secondary
Malignant	Primary
Inflammatory	Hernias
Diverticulitis	Internal
Ulcerative colitis	External
Crohn's disease	Adhesions
Amebiasis	Mass compression
Tuberculosis	Carcinomatosis
Intussusception	Abscess
Obturation	Pregnancy
Gallstones	Cysts

Post-traumatic events	
Pneumatosis intestinalis	

TABLE 62-2 Incidence of Colonic Obstruction by Cause

Cause	Incidence (%)
Carcinoma	55
Volvulus	11
Diverticulitis	9
Extrinsic cancer	8
Adhesions	4
Impaction	3
Hernia	2
Intrinsic	4

CLINICAL FINDINGS

Because most colonic obstructions are caused by cancer, patients are usually older adults and have symptoms related to tumor location. Signs and symptoms are often insidious with right colon lesions because the lumen is large and the contents are semiliquid. These patients often present with pain, a palpable mass, and anemia.¹⁷ Left-sided lesions cause progressive constipation and, ultimately, obstipation, with abdominal distention and pain. If the ileocecal valve is incompetent, retrograde decompression produces the gradual onset of distention and, eventually, feculent vomiting.^{18,19} Lesions occurring at the ileocecal valve or ileocolic intussusception cause more acute symptoms of small bowel obstruction—abdominal pain, distention, vomiting, and obstipation.^{18,19} Patients with volvulus may develop pain and distention rapidly if a closed loop obstruction and bowel ischemia are present.²⁰ On physical examination, an abdominal mass may be present (e.g., advanced right-sided colon cancer) and distention may be most marked in one region (e.g., the left upper quadrant in cecal volvulus). Bowel sounds are often hyperactive, particularly with superimposed small

Figure 62-1 Importance of the ileocecal valve to the radiologic findings in large bowel obstruction. If the ileocecal valve is competent (left), pronounced cecal dilation can occur. An incompetent valve (right) allows retrograde decompression into the small bowel. (From Welch JP [ed]: *Bowel Obstruction*. Philadelphia, WB Saunders, 1990.)

bowel obstruction. Marked tenderness or rebound suggests perforation or strangulation.^{18,19}

RADIOLOGIC APPROACH TO SUSPECTED LARGE BOWEL OBSTRUCTION

Radiography

Abdominal radiographs obtained in the supine and erect or left lateral decubitus positions are often the initial means of imaging patients with suspected obstruction.²¹ These radiographs may confirm the diagnosis, locate the site of obstruction and, in some cases, identify the nature of the obstructing lesion.²²⁻²⁵ The colon is usually dilated proximal to the obstruction; however, if the ileocecal valve is incompetent, the appearance may mimic that of small bowel obstruction.²⁶⁻²⁸ The radiographic findings on plain radiographs in bowel obstruction are discussed in detail in Chapter 10.

Contrast Enemas

If the plain abdominal radiographs show convincing evidence of large bowel obstruction caused by volvulus or ileocolic intussusception, a contrast enema, preferably with a water-soluble medium, is the next step in patients with suspected large bowel obstruction. Although barium is inherently a better contrast agent, it may interfere with future studies, such as computed tomography (CT) or colonoscopy. If the patient proves to have a pseudo-obstruction rather than true obstruction, the barium may remain within the colon for days.²⁹ A water-soluble enema can also be therapeutic in patients with fecal impactions.²⁹ Because oral barium can inspissate proximal to a partial or complete large bowel obstruction, it is important to exclude an obstructing colonic lesion before the small bowel is examined with barium.^{30,31}

Computed Tomography

CT is now the imaging modality of choice for patients with known or suspected obstruction. It is the best noninvasive means of answering the following key questions:

- Is the bowel obstructed?
- What is the level of the obstruction?
- What is the cause of the obstruction?
- Is the obstruction simple or closed loop?

- Are ischemic changes present?
- Does the patient need immediate surgery, or should a trial of conservative therapy be attempted first?

CT is most valuable when there are systemic signs suggesting infection, bowel infarction, or an associated palpable mass.³² CT identifies bowel obstruction as distended bowel loops seen proximal to collapsed loops and can reveal the cause of obstruction, such as tumor, volvulus, diverticulitis, or appendicitis.³³ The transitional zone should be carefully evaluated for masses.³²

Ultrasonography and Magnetic Resonance Imaging

Although CT is the best examination for evaluating patients with suspected colon obstruction, ultrasonography and magnetic resonance imaging (MRI) can also determine the level and cause of obstruction, particularly in children and pregnant women.^{34,35}

MAJOR TYPES OF COLONIC OBSTRUCTION

Carcinoma of the Colon

Large bowel obstruction is caused by intrinsic colon carcinoma in approximately 55% of cases.^{36,37} Almost 20% of colon cancers are complicated by some degree of obstruction; 5% to 10% are complicated by complete obstruction, which requires emergent

surgical intervention.³⁸ The mortality rate is high (10%-30%) in patients requiring emergency surgery, regardless of the site of tumor.^{38,39} This is a reflection of advanced tumor stage, advanced patient age, and associated cardiorespiratory disease, malnutrition, sepsis, and surgical stress.^{40,41} Mortality is even higher if there is concurrent perforation. Patients who present with obstructing colon carcinoma have low curability and survival rates because of advanced disease at the time of diagnosis.⁴²

The sigmoid colon is the most common site of obstructive colon cancer because of its relatively narrow diameter and solid fecal contents. The location of obstruction in one series was as follows: cecum, 11%; right colon, 5%; hepatic flexure, 3%; transverse colon, 11%; splenic flexure, 12%; descending colon, 10%; sigmoid colon, 35%; and rectum, 13%.³⁷ The ratio of obstructing carcinomas to total tumors is similar in the right (Fig. 62-2) and left colon but lower for rectal lesions.¹⁷ Tumors of the transverse colon and splenic flexure are at particular risk for obstruction before clinical detection.⁴³ The risk of developing obstruction in tumors at a particular site has been estimated as 50% for splenic flexure lesions, 25% for right- and left-sided ones, and 6% for rectal tumors.^{17,44} Perforation occurs in 3% to 8% of patients with malignant obstruction.³⁸ The most common site of perforation is the cecum rather than adjacent to the tumor.^{45,46}

Figure 62-2 CT in the evaluation of large bowel obstruction. **A.** Axial image shows an enhancing, obstructing mass (arrow) at the junction of the descending colon and sigmoid colon. **B.** Coronal reformatted image demonstrates the obstructing cancer (arrow) and dilated, fluid-filled colon, and small bowel. **C.** Sagittal depiction of the cancer (arrow) and dilated, fluid-filled colon, and small bowel.

The clinical presentation of obstructive colon cancer depends on the location, duration, and completeness of obstruction, as well as on the competency of the ileocecal valve. Tumors located near the ileocecal valve can produce symptoms suggesting a distal small bowel obstruction. Some right colon tumors act as lead points for colocolic intussusception; others may perforate, causing abscess formation and obstruction. Left-sided colon tumors tend to obstruct in an annular fashion or by a polypoid lesion that reaches a size sufficient to obstruct the lumen. The rectum is not a common site of obstruction because of its greater diameter and distensibility and because rectal cancers often cause rectal bleeding, prompting earlier medical attention. The usual treatment of obstructive colon cancer is surgical resection or diverting colostomy; however, expandable metallic stents can be used for palliation or to allow bowel cleansing before surgical resection.^{47,48}

Diverticulitis

Large bowel obstruction is the result of diverticular disease in about 12% of cases. Diverticulitis can cause small and large bowel obstruction. Partial colonic obstruction can complicate acute diverticulitis as a consequence of edema and pericolic inflammation or abscess formation. High-grade obstruction is uncommon; it is far more frequently caused by carcinoma of the colon. Usually, obstruction follows recurrent attacks of diverticulitis, with marked fibrosis of the colon wall leading to narrowing and eventually stricture formation. The site of obstruction is usually in the sigmoid colon, near the site of inflammation. Obstruction of the transverse or right colon attributable to diverticulitis is rare.^{49,50}

Clinically, patients with sigmoid diverticulitis complain of left lower quadrant pain, fever, and abnormal bowel habits. It is important for these symptoms to be differentiated from those of carcinoma of the colon, an often difficult task clinically and radiologically (Fig. 62-3 and Table 62-3). Symptoms of sigmoid colon cancer are usually more insidious, with rectal bleeding, constipation, and weight loss.⁵¹⁻⁵⁶ A more complete discussion of diverticular disease can be found in Chapter 55.

Volvulus

Volvulus refers to torsion or twist of an organ on a pedicle to a degree sufficient to cause symptoms. Large bowel volvulus (Fig. 62-4) accounts for about 10% of colon obstructions and can affect the sigmoid colon (Fig. 62-5), cecum (Figs. 62-6 and 62-7), transverse colon and, rarely, the splenic flexure. Symptoms are caused by narrowing and obstruction of the gut, strangulation of the blood vessels, or both.⁵⁷⁻⁵⁹

The major predisposing factors necessary for colonic volvulus are a segment of redundant mobile colon on a mesentery or mesocolon and a fixed point around which rotation can occur. The sigmoid colon (Fig. 62-8) is therefore the most frequent site of colonic volvulus, especially in patients older than 60 years.^{60,61} Sigmoid volvulus is not caused by a congenital defect but by dietary and behavioral factors, including increased fiber in the diet, which increases the bulk of stool and elongates the colon. Cecal or ascending colon volvulus occurs in patients with a congenital defect in attachment of the right colon or postpartum ligamentous laxity and a mobile cecum.⁶² Anything that causes colon distention, including pseudo-obstruction, distal tumor, endoscopy, enemas, and postoperative ileus, may precipitate cecal volvulus in susceptible individuals. Transverse colon volvulus occurs in patients with a redundant transverse

Figure 62-3 Sigmoid diverticulitis versus carcinoma: barium enema findings. A. Carcinoma in diverticular disease. **B.** Stricturing attributable to diverticular disease. (From Bartram CT, Kumar P: *Clinical Radiology in Gastroenterology*. Oxford, England, Blackwell Scientific, 1981, p 132.)

TABLE 62-3 Radiologic Differentiation of Sigmoid Diverticulitis from Carcinoma

Diverticulitis	Carcinoma
Spastic bowel	Normal adjacent bowel
Cone-shaped edges	Sharp margins, shelflike
Long segments	Short segments
Mucosa preserved	Mucosa destroyed
Variable constriction between examinations	Progressive obstruction
Diverticula present	Occasional diverticula
Obstruction without tumor	Obstruction with tumor

colon on a long mesentery,⁶³ and splenic flexure volvulus occurs in patients with deficiency of the normal attachments of the splenic flexure to the posterior peritoneal wall, usually as a result of prior surgery.^{64,65} The frequency of colon volvulus is as follows: sigmoid colon, 50% to 75%; cecum, 25% to 40%; and transverse colon, 0% to 10%. A rare cause of combined colon and small bowel obstruction is the ileosigmoid knot.⁶⁶⁻⁶⁸ A detailed discussion of colonic volvulus and its conventional radiographic features can be found in Chapter 10.

On CT, a whirl sign has been described in volvulus. The whirl is constituted by the afferent and efferent limbs leading into the volvulus. Tightly twisted mesentery and bowel compose the central portion of the whirl. The progressive tapering of the two limbs leading to the twist on CT corresponds to the so-called beak seen on barium enema. The distended and redundant sigmoid colon may overlie the liver and extend cephalad to the transverse colon (the so-called northern exposure sign).⁶⁹⁻⁷¹

Figure 62-4 The three major sites of colonic volvulus.

A. Sigmoid volvulus. Adjacent middle walls of the dilated sigmoid colon (SC) form a double line on radiographs that converges on the point of twist in the sigmoid mesocolon. **B.** Transverse colonic volvulus. The caudal border of this ptotic colon is rounded, and the central double bowel wall does not extend to the sigmoid mesentery. **C.** Cecal volvulus. The dilated cecum twists clockwise, obstructing the ascending colon, and the terminal ileum (TI) swings around the dilated bowel. AC, Ascending colon; DC, descending colon; TC, transverse colon.

**Figure 62-5 Sigmoid volvulus: intraoperative image.** A massively dilated sigmoid colon is identified twisted on itself.

Adult Intussusception

Intussusception is defined as the invagination of one segment of the gastrointestinal (GI) tract into an adjacent one (Fig. 62-9). It accounts for 80% to 90% of bowel obstruction in infants and children and ranks second only to appendicitis as the most common cause of an acute abdominal emergency in children. In children, intussusception usually begins in the distal ileum, and in 90% of cases the cause is idiopathic.^{1-4,20} A complete discussion of childhood intussusception can be found in Chapter 121.

In contrast, intussusception in adults accounts for only 1% to 3% of mechanical intestinal obstruction, and a demonstrable cause is found in 80% of adult cases. Colonic intussusception is usually caused by a primary colon cancer, whereas small bowel intussusception is generally related to a benign tumor and less often to a malignancy, usually a metastatic lesion.⁷²⁻⁸⁴ Postoperative intussusceptions usually occur in the small bowel and are related to a number of factors, such as suture lines, ostomy closure, adhesions, long intestinal tubes,

bypassed intestinal segments, submucosal edema, abnormal bowel motility, electrolyte imbalance, and chronic dilation of the bowel.^{84,85}

Benign lesions that can serve as lead points in colonic intussusception include adenomatous polyps, lipomas, gastrointestinal stromal tumors (Fig. 62-10), appendiceal stump granulomas, and villous adenomas of the appendix.⁸⁴ The normal appendix may transiently intussuscept, although clinically significant appendiceal intussusception usually occurs in the setting of appendiceal inflammation, infestation, neoplasm, or endometriosis deposition.⁸⁶ A more complete discussion of diseases of the appendix can be found in Chapter 56. Colonic intussusception has also been reported as a complication of eosinophilic colitis, epiploic appendagitis, and pseudomembranous colitis.⁸⁷⁻⁸⁹

In children, the diagnosis is suggested by the presence of an abdominal mass and passage of blood per rectum. Because adult intussusception is often chronic and relapsing, the diagnosis is suggested by recurrent episodes of subacute obstruction and variable abdominal signs. During the height of an attack, a palpable mass may be present but may disappear completely when the patient is reexamined several hours later, by which time the symptoms have resolved.^{3,20} In infants and young children, hydrostatic or pneumatic intussusception reduction should be attempted and may be definitive therapy because the cause is usually idiopathic. In adults, the high incidence of organic lesions, often malignant, precludes this approach.

If the intussusception is of the ileocolic or colocolic variety, the pathognomonic crescent sign may be seen. This sign is produced when the intussusciens invaginates into the intussusceptum and stretches the outer wall. Intraluminal gas trapped between the two intestinal surfaces can appear as a semilunar lucency lacking haustral septa or valvulae conniventes. This lucent crescent is wider than normal bowel in diameter and is often superimposed on a round soft tissue density representing the mass created by the intussusception. A more central and less distinct lucency may be seen, representing gas trapped in the lumen of the intussusciens. On supine views, the transverse colon gas shadow is often absent because this segment of colon is usually displaced distally.^{21,90,91}

Figure 62-6 Cecal volvulus: plain radiograph and barium enema features. **A.** A distended cecum (arrows) is present in the left lower quadrant. Dilated small bowel is evident proximally. There is a relative paucity of colonic gas distal to the volvulus. **B.** Barium enema shows the contrast column ending abruptly (arrow) at the level of the twist.

Figure 62-7 Cecal volvulus: CT features. **A.** Scout image shows that a distended cecum (arrows) is present in the left upper quadrant, with multiple dilated small bowel loops in the right upper quadrant. **B.** CT scan demonstrates the malpositioned cecum (arrows) and swirling of the mesentery.

Figure 62-8 Sigmoid volvulus. **A.** Scout image shows a markedly dilated sigmoid colon (arrows). The apex of the sigmoid colon lies adjacent to the diaphragm, the northern exposure. **B.** CT scan of the abdomen shows a beak-shaped transition point (arrows). **C.** Coronal reformatted CT image shows the transition zone and swirling of the sigmoid mesocolon (arrows) at the site of the volvulus.

Figure 62-9 Intussusception. Longitudinal (**A**) and cross-sectional (**B**) diagrams of antegrade intussusception. DL, distal intestinal loops; IM, intussuscepted mesentery; IR, intussusciens; IV, intussusceptum; M, mesentery; PL, proximal intestinal loops. (From Iko BO, Teal JS, Siram SM, et al: Computed tomography of adult colonic intussusception: Clinical and experimental studies. *AJR* 143:769-772, 1984.)

Figure 62-10 Ileocolic intussusception. The ileum is intussuscepting (arrow) into the colon. The lead point was a small gastrointestinal stromal tumor of the distal ileum.

The classic appearance of intussusception on barium studies is the coil spring appearance as contrast is trapped between the intussusceptum and intussusciens (Fig. 62-11).

Ultrasound shows a target-like lesion (Fig. 62-12), in which the hypoechoic halo is produced by the mesentery and edematous wall of the intussusciens, and the hyperechoic center is produced by multiple interfaces of compressed mucosal, submucosal, and serosal surfaces of the intussusceptum. Multiple concentric rings, best seen on transverse scans, are also characteristic. The corresponding appearance on longitudinal scans is that of multiple, thin, parallel, hypoechoic, and echogenic stripes.⁹²⁻⁹⁶

On CT, intussusceptions appear as three different patterns, which reflect their severity and duration: (1) the target sign; (2) a sausage-shaped mass, with alternating layers of low and high attenuation; and (3) a reniform mass. Pathophysiologically, the target is the earliest stage of intussusception. As it progresses, a layering pattern develops, with alternating low-attenuation (mesenteric fat) and high-attenuation areas (bowel wall), (Fig. 62-13). If intussusception is untreated, edema and mural thickening develop. An intussusception with a reniform appearance is caused by severe edema and vascular compromise, which constitutes a surgical emergency.⁹⁷ Intussusception is almost invariably associated with acute intestinal obstruction or partial and recurrent obstruction, air-fluid levels, and proximal bowel distention. The mesenteric arcade associated with the intussusciens may show traction. If infarction occurs, this

mass may be surrounded by intraperitoneal fluid, edema, hemorrhage in the mesentery, and even perforation.⁹⁸⁻¹⁰⁴ CT can diagnose lipoma as the lead point; however, with varying degrees of infarction and fat necrosis, lipomas may have an atypical appearance.^{105,106}

Adhesions

Adhesions are the result of inflammation that heals with fibrosis. They are usually the result of surgical trauma but may be congenital. Adhesional large bowel obstruction is unusual because the colon is characteristically fixed and of large caliber and has thick walls. The small bowel, in contrast, has an inherently small caliber and high degree of mobility and is therefore very prone to obstruction by adhesions. A more complete discussion of small bowel obstruction can be found in Chapter 46. The mobile redundant portions of the colon are most likely to be involved.¹⁰⁷ Adhesive obstructions of the right colon, transverse colon, and sigmoid colon have been reported.^{108,109}

Folding of the cecum on itself, the cecal bascule, often occurs at the site of an adhesive band.¹¹⁰ The ascending colon can be obstructed by congenital bands or adhesions caused by inflammatory changes after colonoscopy and polypectomy.^{111,112} Inflammation of the appendices epiploicae can rarely cause obstruction in the rectosigmoid, and ischemia and inflammation of the greater omentum can cause obstruction in the transverse colon.^{113,114} On barium enema, adhesions can appear as an area of circumferential narrowing, usually short, with intact

Figure 62-11 Colonic intussusception: barium enema findings. A cecal neoplasm is intussuscepting into the ascending colon (arrow). Note the coiled spring appearance (arrowheads).

Figure 62-12 Intussusception: sonographic findings. This color Doppler scan, longitudinally imaging the intussusception, shows a central hypoechoic area that is the intussusceptum telescoping into the intussusciens.

Figure 62-13 Colonic intussusception: CT findings.

A. The lead point of this colonic intussusception is a lipoma (arrow). The outer layer represents the intussusciens and the inner layer represents the intussusceptum. **B.** In a different patient, the cigar-shaped intussusceptum (arrow) is seen within the intussusciens.

mucosa, or as a smooth, broad-based filling defect. They may produce partial or complete colonic obstruction.¹¹⁵

Hernias

Hernias cause large bowel obstruction less often than small bowel obstruction because of the relatively fixed nature of the colon and its larger caliber. Inguinal, femoral, umbilical, spigelian, incisional, lumbar, and diaphragmatic hernias (congenital or post-traumatic) can all contain colon and cause bowel obstruction.¹¹⁶⁻¹²⁵ Internal hernias, such as through the foramen of Winslow, can contain colon and cause obstruction as well.¹²⁶⁻¹²⁹ The diagnosis may be made by radiography, barium enema, or CT. A complete discussion of hernias can be found in Chapter 112.

Obturation Obstruction

The terminal ileum is the narrowest portion of the gut and, as a result, is the most common site of obturation obstruction. The sigmoid colon, measuring 2.5 cm in diameter, only slightly larger than the distal ileum, is the narrowest portion of the colon, followed by the hepatic and splenic flexures. These are the most likely points of colonic impaction of an intraluminal object.¹³⁰

Of patients with gallstone ileus, 3% to 5% have colonic obstruction.¹³¹ In these patients, the gallstone most often bypasses the ileocecal valve through a cholecystocolic fistula and usually impacts in the sigmoid colon, which may be narrowed by prior diverticulitis.¹³²

Bezoars, foods, and enteroliths usually do not obstruct the colon unless there is a stricture.^{133,134} Patients with cystic fibrosis (see Chapter 118) tend to form large cecal masses of inspissated feces that can cause the meconium ileus equivalent syndrome.¹³⁵

Sufficient amounts of various medications or diagnostic agents can cause colonic obturation obstruction. Antacid impactions containing nonabsorbable aluminum hydroxide antacid gels, given to prevent hyperphosphatemia, can develop in the right colon of patients with renal failure. These impactions can be treated with orally or rectally administered hyperosmolar diatrizoate meglumine (Gastrografin).¹³⁶

Barium retained in the colon for several days is desiccated and can form impactions in any part of the colon, usually the proximal portion. These impactions can also be treated by hyperosmolar Gastrografin, which stimulates peristalsis and draws fluid into the bowel.^{137,138} Foreign bodies entering via an oral or transanal route can cause obstruction or perforation.¹³⁹

Older, inactive, debilitated, and mentally challenged patients, drug addicts in methadone maintenance programs, transplantation and hemodialysis patients, and those with adult Hirschsprung's disease are at risk for developing fecal

BOX 62-1 COLONIC ISCHEMIA: RISK FACTORS

- Inferior mesenteric artery ligation, thrombosis, or embolus
- Superior mesenteric artery ligation, thrombosis, or embolus
- Cardiac arrhythmia
- Congestive heart failure
- Shock
- Digitalis toxicity
- Collagen vascular disease
- Strangulated hernia
- Oral contraceptives
- Polycythemia vera
- Trauma
- Diabetes
- Amyloidosis
- Radiation

impaction. The most common sites are the rectum (70%) and sigmoid colon (20%). A fecaloma or stercoroma is a mass of fecal material that develops the characteristics of an intraluminal tumor. These are composed primarily of an accumulation of undigested food forming a nucleus around which fecal material accumulates. Obstruction, volvulus, stercoral ulceration, perforation, rectal prolapse, and rectal fissure are potential complications of fecalomas.^{140,141}

Strictures

Colonic strictures can result from a variety of disorders (Boxes 62-1 to 62-3). These strictures often cause chronic obstructive symptoms and may cause acute obstruction from the presence of impacted feces or as a result of obturation in the stricture by a foreign object.

Other Causes

Pelvic lipomatosis, in which there is benign fatty tissue infiltration into the perirectal and perivesical spaces, usually causes straightening, narrowing, and rigidity of the rectum but occasionally can cause obstruction.¹⁴² Pregnancy, mesenteric cysts, wandering spleen, retroperitoneal tumors, retractile mesenteritis, and retroperitoneal fibrosis are rarer causes of large bowel obstruction.¹⁴³⁻¹⁴⁵

Extracolonic Diseases Involving the Colon

Benign and malignant extrinsic disease processes can involve the colon. Endometriosis, ovarian carcinoma, other benign and malignant gynecologic diseases, pancreatic disease, prostate

BOX 62-2 GENERAL, SYSTEMIC, AND PSYCHOLOGIC CAUSES OF CONSTIPATION

LIFESTYLE

- Inadequate fiber
- Little food
- Repressing or ignoring urge to defecate
- Immobility

EXTERNAL FACTORS

- Drugs (including opiates, anticholinergics, antidepressants, anti-convulsants)

ENDOCRINE AND METABOLIC FACTORS

- Hypothyroidism
- Hypercalcemia
- Porphyria
- Neurologic
- Parkinson's disease
- Multiple sclerosis
- Spinal lesions
- Damage to sacral parasympathetic nerves
- Autonomic neuropathy
- Autonomic failure

PSYCHOLOGIC FACTORS

- Depression
- Eating disorders (e.g., anorexia nervosa)
- Obsession about "inner cleanliness"
- Denied bowel actions

From Lembo AJ, Ullman SP: Constipation. In Feldman M, Friedman LS, (eds): *Gastrointestinal and Liver Disease*, 9th ed. Philadelphia, Saunders, 2010, pp 259–284.

BOX 62-3 GASTROINTESTINAL CAUSES OF CONSTIPATION AND RELATED SYMPTOMS

GASTROINTESTINAL TRACT

- Obstruction
- Aganglionosis (Hirschsprung's disease, Chagas' disease)
- Myopathy
- Neuropathy
- Systemic sclerosis

MEGARECTUM AND COLON

- Anal atresia or malformation
- Hereditary internal anal sphincter myopathy
- Anal stenosis
- Weak pelvic floor
- Large rectocele
- Internal intussusception
- Anterior mucosal prolapse
- Prolapse
- Solitary rectal ulcer

From Lembo AJ, Ullman SP: Constipation. In Feldman M, Friedman LS, (eds): *Gastrointestinal and Liver Disease*, 9th ed. Philadelphia, Saunders, 2010, pp 259–284.

carcinoma, and other abdominal malignancies can present as colon involvement. This involvement may cause obstruction and can mimic primary colon pathology. Obstruction usually occurs in the pelvis, where the colon is fixed and confined by the bony pelvis. The transverse colon is another common site

of involvement because of its omental and mesenteric attachments (see Chapter 108). Barium enema, CT, and endoscopic ultrasonography may be helpful in the assessment of colonic wall invasion by adjacent disease processes.¹⁴⁶

ENDOMETRIOSIS

Endometriosis is a disease that affects 8% to 18% of women during their active menstrual years, usually between the ages of 30 and 45 years.^{147,148} GI tract involvement has been reported in 5% to 37% of patients.¹⁴⁹ In one large retrospective review of over 7000 patients with endometriosis, 12% of the patients had gut involvement. The rectosigmoid colon was the most frequently involved site (72% of cases), followed by the rectovaginal septum (14%), small intestine (7%), cecum (4%), and appendix (3%).¹⁵⁰ Rare cases of involvement of the stomach, pancreas, proximal small bowel, and transverse colon have been reported.

The anterior wall of the rectosigmoid colon adjacent to the pouch of Douglas is the most frequent site of GI tract involvement. Endometrial implants on the bowel are usually extrinsic or serosal but may be intramural or, rarely, intraluminal.¹⁵¹ Implants typically appear as an extrinsic serosal mass effect with mucosal preservation on double-contrast barium enema studies (Fig. 62-14). This appearance, although characteristic of endometriosis, is not specific because other extrinsic processes in the cul-de-sac, such as drop metastases or an abscess, can produce an identical appearance. Serosal spiculation and fine crenulations of the mucosa can usually be identified when there is involvement of the bowel wall.¹⁵² Less frequently, manifestations of endometriosis on barium enema are a polypoid mass extending into the lumen of the colon, stricture, or short annular lesion. These cases may be difficult to distinguish clinically and radiographically from carcinoma.¹⁵³ Rarely, endometriosis presents as acute obstruction, GI bleeding, or perforation, necessitating resection.^{7,154-157} Endometriomas usually appear as solid or complex cystic masses on ultrasound or CT, but the appearance is not specific and may be indistinguishable from a neoplasm or abscess.¹⁵⁸⁻¹⁶⁰ MRI (see Fig. 62-14) is more sensitive and specific for detection of hemorrhage within these masses.¹⁶⁰

MALIGNANT GYNECOLOGIC TUMORS

Malignant gynecologic neoplasms spread within the peritoneal cavity by direct invasion, intraperitoneal seeding, hematogenous metastasis, and lymphatic extension. Intraperitoneal seeding of malignant cells is dependent on the natural pathways of flow of ascitic fluid as demonstrated by Meyers.¹⁶¹ The characteristic patterns of spread vary depending on the origin of the primary tumor. See Chapter 109 for a more complete discussion of pathways of abdominal and pelvic spread of disease.

OVARIAN CARCINOMA

Ovarian carcinoma is the fifth leading cause of cancer deaths in women; the prevalence increases with age and peaks around age 60 years.¹⁶²⁻¹⁶⁴ Most patients with ovarian carcinoma have relatively few symptoms, and in over 50% the disease is in an advanced stage at the time of initial presentation. Patients usually have vague abdominal symptoms and present with

increasing abdominal girth and a large palpable mass, although some tumors are detected earlier on routine pelvic examination. Occasionally, intestinal symptoms or colonic obstruction may be the first manifestation of ovarian cancer.¹⁶⁵

Ovarian carcinoma is the most common primary malignancy to invade the colon directly. The subperitoneal space forms a pathway for the spread of disease processes from the pelvis to the abdomen.^{166,167} Direct invasion from the left ovary through the sigmoid mesocolon usually involves the inferior border of the sigmoid colon. Direct invasion from the right ovary usually involves the cecum and distal ileum by means of extension through the small bowel mesentery of the ileum. Direct invasion of the colon by ovarian cancer can be readily

demonstrated on barium enema, with appearances ranging from serosal spiculation with tethering and fixation to gross invasion and annular constriction to complete obstruction.¹⁶⁸ Mural involvement may produce narrowing with mucosal crenulations or, in more severe cases, marked narrowing with spiculation. Annular constriction may simulate carcinoma or diverticulitis, and complete obstruction may mimic an obstructing colon carcinoma.

Ovarian carcinoma frequently spreads by intraperitoneal seeding. The colon is the portion of the GI tract most frequently involved by intraperitoneal seeding of ovarian carcinoma. Peritoneal implants, which may be multiple, are seen as extrinsic masses, often with serosal spiculation and tethering (Fig. 62-15)

Figure 62-14 Pelvic endometriosis. **A.** Barium enema examination shows an extrinsic mass on the serosal aspect of the rectum (arrow). **B.** Pelvic ultrasound depicts a well-margined pelvic mass (arrow) with multiple fine, homogenous, low-level echoes. **C.** Sagittal MRI scan demonstrates invasive endometriosis along the anterior aspect of the rectum (arrow).

Figure 62-15 Ovarian carcinoma. **A.** Sagittal T2-weighted MRI scan shows a complex cystic mass (yellow arrow) compressing the anterior wall of the rectum (red arrow). **B.** In a different patient with ovarian carcinomatosis, multiple serosal implants (arrows) are identified along the medial aspect of the sigmoid colon.

on barium enema studies. An implant in the cul-de-sac may be indistinguishable from an abscess or endometrioma. In addition, ovarian carcinoma frequently seeds the greater omentum, producing a so-called omental cake, which can secondarily involve the transverse colon or stomach. The appearance in these cases can simulate gastric cancer with extension to the transverse colon through the gastrocolic ligament or colon cancer with extension to the stomach.¹⁶⁹⁻¹⁷¹

OTHER GYNECOLOGIC MALIGNANCIES

Cervical carcinoma spreads by direct extension to the pelvic sidewall and adjacent structures, including the rectum. Demonstration of rectal involvement is an important finding because hysterectomy is reserved for patients with tumor localized to the cervix or extension confined to the parametrium or upper two thirds of the vagina (stage IIB or less). All others are treated with radiation therapy.¹⁷²

Carcinoma of the endometrium, vagina, and fallopian tubes can also invade the rectosigmoid colon directly. Barium enema examination provides important information for staging and planning surgical resection of these pelvic malignancies. These tumors can also spread by peritoneal seeding or lymphatic extension. Leiomyosarcoma of the uterus, like other sarcomas, may spread by hematogenous metastasis to the gut, producing submucosal masses that can ulcerate and bleed.

BENIGN GYNECOLOGIC TUMORS

Benign ovarian tumors, including serous and mucinous cystadenomas and teratomas, may produce an extrinsic impression on the rectosigmoid colon that is recognizable on CT and barium enema. These masses, which are purely extrinsic to the bowel, have a smooth interface with the colonic wall and are usually asymptomatic but, if very large, may produce symptoms of partial obstruction. Teratomas usually contain fat or calcification that can be detected on plain films or CT. Uterine fibroids are present in 25% to 50% of women and are the most common pelvic tumor, with a peak incidence in the fifth decade of life. Most are small and asymptomatic. Fibroids may present as vaginal bleeding if they are submucosal or may become symptomatic if they grow to a large size. Barium enema in these cases demonstrates a smooth extrinsic mass effect on the sigmoid colon, with marked displacement and stretching of the colon if the tumor is large. Rupture of an ovarian cystadenoma into the peritoneal cavity may result in pseudomyxoma peritonei.

PELVIC INFLAMMATORY DISEASE AND TUBO-OVARIAN ABSCESS

Pelvic inflammatory disease has a variety of causative organisms, including *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, and a number of other aerobic and anaerobic bacteria. The tubo-ovarian abscesses that result may secondarily involve the bowel and may be indistinguishable on barium enema from endometrial or metastatic implants on the serosal surface. The cul-de-sac is a frequent site of involvement. Ultrasonography, CT, or MRI shows a thick-walled fluid collection that may be difficult or impossible to differentiate from cystic neoplasm or endometrioma.^{173,174}

SEXUALLY TRANSMITTED DISEASES

Lymphogranuloma venereum is a sexually transmitted disease caused by infection of lymphatic tissue by *C. trachomatis*. The site of primary infection is usually around the genitals, but the rectum may be the primary site of involvement. Primary infection of the rectum is usually acquired by anal intercourse, but proctitis may also result from the spread of an infected vaginal discharge to the anal canal or by lymphatic extension from inguinal lymph nodes. Patients present with inguinal adenopathy and deep rectal ulceration. The disease may progress to form a fistula, perirectal abscess, or stricture (Fig. 62-16).¹⁷⁵ Other sexually transmitted diseases, including *N. gonorrhoeae* or herpes simplex infection and syphilis, can infect the rectum and cause proctitis.¹⁷⁶ Barium enema demonstrates mucosal ulceration or a granular mucosal pattern. CT typically shows non-specific mural thickening of the rectum and anus.

PANCREATITIS

Approximately 1% of patients with acute pancreatitis have significant colonic problems. These complications usually occur 10 to 21 days after disease onset and may relate to compression caused by a pancreatic phlegmon or abscess and widespread fat necrosis, or by mural thickening caused by edema and necrosis secondary to pancreatic enzymes dissecting down the transverse mesocolon or phrenicocolic ligament.¹⁷⁷ Occasionally, a high-grade obstruction or perforation may occur that requires surgical intervention.¹⁷⁸⁻¹⁸² For a more complete discussion of pancreatitis, see Chapter 97.

METASTASES

High-grade colonic obstruction is attributable much less often to metastatic than to primary tumors.¹⁸³ Renal and prostate neoplasms can directly invade the colon.¹⁸⁴ Carcinoma of the prostate involves the rectum in 0.5% to 11% of cases and may simulate rectal carcinoma clinically. Rectal obstruction occurs when there is direct extension through the thick, double-layered

Figure 62-16 Chlamydial infection (lymphogranuloma venereum). Barium enema examination demonstrates a stricture of the rectum, with fistulas and sinus tracts.

Denonvillier's fascia or by rectal compression caused by a massively enlarged prostate gland.^{185,186} Gastric and pancreatic neoplasms can invade the colon directly or narrow it by serosal metastases.¹⁸⁷⁻¹⁸⁹

Colonic Ischemia

CLINICAL FINDINGS

Colonic ischemia is the most common vascular disorder of the GI tract and the most common cause of colitis in older adults.^{189,190} Although many conditions have been implicated in the pathogenesis of colonic ischemia (see Box 62-1), the cause is unclear in most patients, and no precipitating event or condition can be identified. Most patients have no major vascular occlusion, so the condition is attributed to low flow states, small vessel disease, or both. In about 20% of cases, an obstructive or potentially obstructive colonic lesion is present.

Colonic ischemia produces a wide spectrum of disease, ranging from gangrene of the colon to transient ischemic colitis. Colonic ischemia is classified as follows: (1) reversible ischemic colopathy; (2) reversible or transient ischemic colitis; (3) chronic ulcerative ischemic colitis; (4) ischemic colonic stricture; (5) colonic gangrene; or (6) fulminant universal ischemic colitis.¹⁹¹

The underlying pathophysiology of colonic ischemia is insufficient blood supply to the bowel to meet the needs of the mucosa. The mucosa receives most of the intestinal blood flow and is most susceptible to damage. Injury may be confined to the mucosa and submucosa or may extend transmurally. The degree of damage depends on the rate of onset of the ischemic event and extent of the vascular deprivation. The outcome may be complete healing, reversible or chronic colitis, stricture formation, or gangrene. About 50% of patients fall into the first category, with mild disease that resolves in 1 to 2 weeks. The clinical course is highly variable. In one series, the outcomes were as follows: reversible hemorrhage and edema, 33%; transient or reversible colitis, 16%; reversible or persistent strictures, 12%; persistent colitis, 21%; and gangrene or perforation, 18%.¹⁹⁰

Most patients with colonic ischemia are older than 50 years and present with mild lower abdominal pain and rectal bleeding or bloody diarrhea. Those with transmural disease have more impressive findings, with peritoneal signs. The frequency of distribution of ischemic colitis is as follows: left colon (32.6%), distal colon (24.6%), right colon (25.2%), transverse colon

(10.2%), and pancolitis (7.3%). The diagnosis is usually based on colonoscopy and CT results.

PATHOLOGIC FINDINGS

Acute ischemic lesions of the colon show necrosis (Fig. 62-17) of the superficial portion of the mucosa, which often spares the deeper portions of the colonic crypts. The remaining crypts typically have an atrophic or withered appearance that reveals striking cytoplasmic atypia, which may be mistaken for dysplasia. Pseudomembranes, hemorrhage into the lamina propria, and hyalinization of the lamina propria may also be seen. These lesions may regress on their own, or frank gangrene with perforation or stricture formation may occur.

The chronic phase of ischemic colitis may be more difficult to diagnose, because the only histologic findings may be areas of submucosal fibrosis and stricture, which are nonspecific.

RADIOLOGIC FINDINGS

Radiography

Abdominal radiographs are usually nondiagnostic and are normal or show a nonspecific ileus. In a series of 41 patients with colonic ischemia, only 21% had radiographic findings suggesting ischemia. Radiographic findings in colonic ischemia include normal, nonspecific ileus, thumbprinting, transverse ridging, and fixed loops with tubulation and lack of haustra. The most characteristic finding on radiographic and barium enema examination is thumbprinting, which consists of multiple round, smooth, scalloped defects projecting into the air-filled colonic lumen (Fig. 62-18). Thumbprinting is caused by submucosal bleeding, edema, or both, and usually occurs within the first 24 hours after the insult to the bowel.¹⁹² Experimental work has shown that thumbprinting results from extravasation of blood around small blood vessels that are reperfused after losing their integrity during the ischemic period.¹⁹⁰ Thickening of the bowel wall secondary to edema and hemorrhage may be observed; this is reflected by luminal narrowing or transverse ridging. As the edema progresses or mucosal sloughing occurs, fixed rigid, tubular, ahaustral loops may develop.¹⁹³ Rarely, pneumatosis or portal venous gas can be identified. These findings generally indicate necrotic bowel.

Barium Enema

Colonoscopy and CT are the primary means of establishing the diagnosis of ischemic colitis. The barium enema findings

Figure 62-17 Ischemic colitis.

A. Colonoscopy shows a diffusely ulcerative, hyperemic mucosa.
B. The mucosal surface of the colon shows necrosis and hyperemia extending from the mucosa to the serosa of the colon. Frank ulceration is present.

Figure 62-18 Colonic ischemia: narrowing and thumbprinting on plain abdominal radiograph. Supine radiograph of the abdomen shows marked narrowing and thumbprinting of the transverse colon (arrows) caused by colonic ischemia.

depend on the extent of the ischemic process, degree of damage, and stage at which the examination is performed. The hallmark of colonic ischemia is serial changes on examinations performed over days, weeks, or months.¹⁹⁴⁻¹⁹⁶

The classic barium enema findings in colonic ischemia are thumbprinting, transverse ridging, spasm, ulceration, intramural barium, and strictures. The most consistent and characteristic finding on the barium enema examination early in the course of the disease is thumbprinting, which is seen in 75% of patients.¹⁹⁶ Thumbprinting on a barium enema study corresponds to the radiographic findings of smooth, round, polypoid, and scalloped filling defects projecting into the opacified colonic lumen as a result of submucosal edema or hemorrhage (Fig. 62-19). Edema and hemorrhage may be soft and compressible, and taking films with maximal distention may affect the findings. Because spasm often accompanies ischemia, maximal distention may be hard to maintain, making thumbprinting easier to see. Careful fluoroscopy with imaging during the filling stage of the examination and postevacuation radiographs should be obtained to document the presence of thumbprinting. Intraluminal pressures during single- and double-contrast examinations are fairly equivalent, so there is no advantage to performing a single-contrast study in this regard. Thumbprinting characteristically resorbs in less than 1 week but may persist for weeks in some patients.¹⁹⁵ Thumbprinting, although characteristic of ischemia, may also be observed in other conditions, including inflammatory bowel disease and the infectious colitides.

Transverse ridging is a less common finding, observed in 13% of patients with colonic ischemia.¹⁹⁵ Transverse ridging is caused by edema or spasm and is characterized by parallel, symmetric thickened folds running perpendicular to the bowel lumen. Like thumbprinting, it is generally an early finding and usually resolves rapidly.¹⁹⁶

Ulceration is present in 46% to 60% of patients with colonic ischemia, and is caused by sloughing of the mucosa.¹⁹⁶ Ulceration generally develops 1 to 3 weeks after the onset of disease and may heal completely, continue into a chronic

Figure 62-19 Colonic ischemia: thumbprinting. Single-contrast barium enema study shows extensive thumbprinting caused by hemorrhage or edema in colonic ischemia.

ulcerative ischemic phase, or heal with stricture formation. The ulcerations are characteristically longitudinal but may also be discrete, superficial, deep, small, or large. Differential diagnosis from other forms of colitis, particularly Crohn's disease and ulcerative colitis, can be made on the basis of sequential changes on barium enema examination, age of the patient, distribution of disease, clinical history, and endoscopic and biopsy findings.¹⁹⁶

Intramural barium is an unusual manifestation of ischemia and is caused by sloughing of a necrotic portion of the wall, with subsequent tracking of barium intramurally. Intramural barium can also be seen in other conditions, such as Crohn's disease and diverticulitis.

About 12% of patients with severe colonic ischemia heal with stricture formation.¹⁹⁰ Strictures can develop rapidly in the course of disease and may be identified as early as 3 weeks after initial presentation. Strictures may be reversible or irreversible and characteristically lead to few obstructive symptoms. In some patients, postischemic strictures may be encountered without a clear antecedent episode. The strictures may be smooth and tapering or eccentric, with sacculations.

About 20% of cases of colonic ischemia occur proximal to an obstructive or potentially obstructive colonic lesion. In about 50% of patients, the lesion is a colon carcinoma; diverticulitis and volvulus are the other major causes. In this setting, the typical findings of thumbprinting and ulceration can

develop or an urticarial pattern can be seen. This consists of bleblike mounds on the mucosal surface caused by early ischemia.¹⁹⁷ It is thought that increased intraluminal pressure proximal to the obstruction decreases mucosal perfusion.

Colonoscopy is useful in the diagnosis of colonic ischemia; the findings vary, depending on the stage at which the examination is performed. Initially, purplish blebs resulting from hemorrhage may be seen, corresponding to the radiographic findings of thumbprinting. As the hemorrhage is resorbed, varying degrees of ulceration, mucosal sloughing, and inflammation develop. The colonoscopic findings at this stage may resemble those in other forms of colitis. As with the barium enema, sequential studies demonstrate a changing pattern.¹⁹⁸

Computed Tomography, Ultrasonography, and Magnetic Resonance Imaging

Because CT is often the initial radiologic procedure in patients presenting with abdominal pain, colonic ischemia may first be suspected on the basis of this study. Symmetric bowel thickening is the major CT finding of colonic ischemia (Fig. 62-20A). In some cases, a target or double halo pattern and polypoid defects associated with thumbprinting may be seen.¹⁹⁹ Mural thickening (>3 mm) of the colon is a nonspecific finding that can also be seen in carcinoma, lymphoma, metastatic disease, diverticulitis, Crohn's disease, and appendicitis. When the ischemia is severe, pneumatosis intestinalis may be seen (Fig. 62-20B; also see later).

Abnormal colonic wall thickening can also be identified by ultrasound.²⁰⁰ Again, this is a nonspecific finding but should lead to further studies of the colon when identified. Doppler ultrasound may show diminished perfusion to the involved segment.²⁰¹⁻²⁰³

Radiation Colitis

The colon is often affected by radiation for pelvic genitourinary tract tumors. Patients with carcinoma of the rectum may also receive radiotherapy before or after surgery. Acute symptoms of

proctitis and diarrhea are common during therapy and usually resolve within weeks after completion of the therapy.

PATHOGENESIS

Radiation can injure and kill cells by two methods. The first is a direct cytotoxic effect, in which the ionizing radiation absorbed by these cells generates a series of biochemical events that progress to cell disruption and death. Free radicals derived from intracellular water interact with DNA to prevent replication, transcription, and protein synthesis. These cytotoxic effects predominate in cells that replicate rapidly. Accordingly, the intestine has the following radiation tolerance (in decreasing order): duodenum, jejunum, ileum, transverse colon, sigmoid colon, esophagus, and rectum. Pathologically, abnormal epithelial cell proliferation and maturation are associated with decrease in crypt cell mitosis. Edema, hyperemia, and extensive inflammatory cell infiltration are often present as well.

The second major mechanism of radiation injury is more insidious and involves damage to the fine vasculature and connective tissue of the intestine. A low-grade ischemia is caused by medial wall thickening and subendothelial proliferation producing endarteritis obliterans of the smallest arterial branches. This chronic ischemia often leads to a fibrotic reaction that can result in contraction, stricture formation, perforation, fistula, or hemorrhage.

The usual dose for treating abdominal and pelvic malignancies is between 3000 and 7000 cGy (1 cGy = 1 rad) and is delivered in fractions over an interval of 4 to 8 weeks. Lower total dosage, lower rates, and smaller treatment volumes minimize damage. Inherent differences in tissue susceptibility also determine which organ is affected most severely by a given dose. Rubin and Casarett have defined the concept of the tolerance dose.²⁰³ A minimal tolerance dose is usually expressed as TD_{5/5}, which represents the total dose that produces radiation damage in 5% of patients within 5 years. This dose has been determined to be 4500 cGy for the small bowel and colon and 5000 cGy for the rectum.²⁰⁵

Figure 62-20 Colonic ischemia: CT findings.

A. Coronal reformat image shows mural thickening with submucosal edema of the splenic flexure of the colon (arrow). **B.** Pneumatosis intestinalis of the right colon (arrows) is identified in this patient with colonic ischemia and infarction.

FINDINGS

Clinical Findings

Radiation colitis typically develops after a 2-year latency period. Patients present with rectal bleeding, pain, and diarrhea, evoking a differential diagnosis that includes recurrent tumor, postoperative stricture in a colonic anastomosis, or regional inflammatory change resulting from pelvic abscess. Proctitis is usually seen sigmoidoscopically.²⁰⁴

Radiologic Findings

In acute radiation colitis, mural thickening of the involved segment of colon may be seen, associated with submucosal edema and hyperenhancement of the mucosa (Fig. 62-21A). In patients with chronic radiation proctosigmoiditis, barium enema examination can show diffuse or focal narrowing of the rectum and sigmoid colon, usually with tapered margins (Fig. 62-21B). The mucosal pattern is usually preserved but may be distorted or disrupted because of edema or intramural hemorrhage resulting from radiation-induced ischemic changes. Rectal stricture or rectovaginal fistula may be seen, and the presacral space is widened on the lateral view of the rectum and on CT.¹⁹⁹⁻²⁰² A recurrent tumor usually produces an eccentric mass effect and mucosal destruction and involves a relatively short segment of the colon. The radiologic differential diagnosis includes ulcerative colitis, Crohn's disease, and scarring by chlamydial proctitis.

TREATMENT

When symptoms such as obstruction or fistula become intolerable, surgical resection may be needed. Initially, a diversion colostomy is formed. After healing has occurred, an abdominal pull-through procedure with coloanal anastomosis between the nonirradiated colon and anus usually provides permanent relief. Attempts to resect strictures or fistulas are less likely to

succeed because of poor healing of the irradiated rectosigmoid tissue. Development of colon carcinoma has been suggested as a possible late sequela of pelvic irradiation.^{201,203}

Vascular Lesions of the Anorectum

INTERNAL HEMORRHOIDS

Internal hemorrhoids are dilated vascular spaces of the internal hemorrhoidal plexus in the submucosal layer of the upper anal canal and lower rectum. Normally, the submucosa of the upper anal canal has three distinct vascular cushions—along the left lateral, right anterior, and right posterior wall.²⁰⁴ It is postulated that these anal cushions aid in anal continence. The pathogenesis of hemorrhoids is multifactorial. With age, the connective tissue tethering the mucosa to the submucosa and muscular layer of the anal canal becomes lax. With excessive straining during defecation, prolapse of anal canal mucosa occurs, leading to congestion of vascular cushions and internal hemorrhoids. Pathologically, internal hemorrhoids appear as thick-walled submucosal veins, with accompanying arteries and dilated capillaries. Abundant arteriovenous anastomoses are present.

Hemorrhoids (piles) are extremely common and can cause brisk rectal bleeding, blood staining on toilet tissue, or painful swelling. With strangulation of hemorrhoids, mucosal infarction, necrosis, and superinfection may occur. Internal hemorrhoids may also be a complication of distal rectal carcinoma. Internal hemorrhoids are not varicose veins, and their incidence is not increased in patients with portal hypertension. Hemorrhoids are frequently diagnosed by digital examination, anoscopy, and flexible sigmoidoscopy.

Internal hemorrhoids have a varying radiographic appearance.^{205,206} When mild lobulation of anorectal folds (the columns of Morgagni) extends less than 3 cm from the radiographic anorectal junction, radiographic diagnosis of internal

Figure 62-21 Radiation-induced proctitis.

A. There is mural thickening with submucosal edema and hyperenhancement of the rectum in this patient with acute radiation proctitis undergoing therapy for rectal cancer. **B.** In a different patient with chronic radiation proctitis, there is a long segment of narrowing in the rectosigmoid demonstrated on this barium enema examination. The presacral space is also widened.

Figure 62-22 Radiographic appearance of internal hemorrhoids. **A.** Lobulated folds. Mild lobulation of anorectal folds (arrowheads) that extends less than 3 cm above the anorectal junction is a typical radiographic finding for internal hemorrhoids. **B.** "Bunch of grapes." Three smooth-surfaced polyps (arrows) are clustered above the anorectal junction. This radiographic appearance is typical of internal hemorrhoids. **C.** Solitary polyp. A smooth-surfaced polyp (arrow) projects from mildly lobulated columns of Morgagni. This is a nonspecific radiographic appearance that requires endoscopy. **D.** Submucosal mass. A smooth-surfaced mass (arrow) with relatively abrupt angulation to the colonic contour is typical of a submucosal mass. Although this is a typical radiographic appearance of internal hemorrhoids, other submucosal rectal masses include lymphoid polyps and solitary rectal ulcers. **E.** Masslike internal hemorrhoid. A large mass (arrows) in the distal rectum has a focally irregular surface pattern. This huge internal hemorrhoid cannot be distinguished from other rectal masses, such as carcinoma or cloacogenic carcinoma. Endoscopy and biopsy are necessary. **F.** Multiple polypoid folds. Large polypoid folds (arrows) with a nodular surface pattern in the distal rectum. Although these radiographic findings are typically seen with internal hemorrhoids, they may also be caused by solitary rectal ulcer syndrome, various forms of proctitis, or an unusual infiltrating tumor.

hemorrhoids is confident (Fig. 62-22A). Another diagnostic appearance of internal hemorrhoids is a cluster of smooth-surfaced polyps smaller than 1 cm abutting the anorectal junction (Fig. 62-22B). Internal hemorrhoids may have nonspecific appearances as well, including a solitary polyp (Fig. 62-22C); solitary submucosal mass (Fig. 62-22D); mass (Fig. 62-22E); or large, infiltrative lobulated folds extending more than 3 cm from the anorectal junction (Fig. 62-22F). Internal hemorrhoids seen as solitary polyps cannot be distinguished from inflammatory, benign, or neoplastic rectal polyps. Internal

hemorrhoids appearing as large, lobulated infiltrative folds extending more than 3 cm above the anorectal junction are indistinguishable from proctitis or infiltrating neoplasm.²⁰⁶

RECTAL VARICES

Rectal varices are a rare cause of lower GI bleeding and are usually seen in patients with portal hypertension. Rectal varices have been associated with adhesions.^{207,208} Radiologically, smooth serpiginous folds course along the rectal mucosa

(Fig. 62-23). When seen in profile, rectal varices may appear as small, smooth-surfaced submucosal nodules. Like esophageal varices, rectal varices may change in size and shape with luminal distention.²⁰⁹

CLOACOGENIC (BASALOID) CARCINOMA

The transitional epithelium of the anal canal contains squamous, transitional, and stratified columnar epithelium, as well as scattered goblet cells. Various neoplasms of controversial origin arise in this transitional epithelium. The transitional zone has features of urothelium and squamous epithelium consistent with a cloacogenic origin.²¹⁰ Hence, many tumors in this region were previously termed *cloacogenic carcinomas*. However, the transitional zone also has features suggesting that it is an area in which metaplasia and reserve cell hyperplasia occur, similar to the transitional zone in the uterine cervix or transitional zone at the esophagogastric junction.²¹¹ Thus, it has also been postulated that tumors in this region are caused by dysplasia and, hence, carcinoma arising in squamous metaplasia and reserve cell hyperplasia. For example, homosexual men have a high incidence of anal transitional cell carcinoma and squamous cell carcinoma in this region. These tumors may be related to venereally transmissible agents, such as oncogenic viruses, carcinogens in lubricants and cleansers, or mechanical irritation.²¹² Tumors at the anorectal junction have been described by a wide variety of names, including squamous cell carcinoma, basaloid carcinoma, transitional cell carcinoma, mucoepidermoid carcinoma, adenoid cystic carcinoma, and verrucous carcinoma. Basaloid carcinoma and cloacogenic carcinoma are probably equivalent terms. Most tumors, however, have a mixture of growth patterns, including basaloid areas, transitional cell carcinomas with squamous differentiation, adenoid cystic carcinoma, and mucoepidermoid carcinoma. The most common tumor of the anal canal is adenocarcinoma of the rectal mucosa invading the anal canal.

Cloacogenic (basaloid) carcinoma has no distinctive clinical, gross pathologic, or radiologic features. Patients usually

complain of rectal bleeding, rectal pain, or a change in bowel habits. These tumors may be flat, infiltrative, annular, or ulcerative lesions, with rolled borders. Radiographically, the tumor may appear as a submucosal mass with a smooth or ulcerated surface (Fig. 62-24), broad-based sessile polyps, or infiltrative lesions (Fig. 62-25).^{211,212}

Metastases occur in approximately 50% of patients to the sacral lymph nodes, internal and common iliac lymph nodes, and superficial inguinal lymph nodes. Venous drainage and hematogenous metastasis are to both the inferior vena cava and the portal system. Five-year survival in patients with basaloid carcinoma is approximately 50%.²¹²

RECTAL MUCOSAL PROLAPSE SYNDROMES

Chronic prolapse of rectal mucosa may result in chronic inflammation, ulceration, and hyperplastic reparative response. During defecation, rectal mucosa passing inferiorly through a contracted puborectalis sling may experience trauma, especially along the anterior and anterolateral wall. Chronic intussusception may also result in mucosal damage. The mucosal response to chronic defecatory problems results in a spectrum of syndromes, including solitary rectal ulcer syndrome, colitis cystica profunda, hypertrophied anal papilla, and inflammatory cloacogenic polyp.²¹³ A similar histologic response may be seen with prolapsing internal hemorrhoids and prolapsing colostomies.²¹³

Solitary rectal ulcer syndrome is an uncommon, chronic benign condition. The term *solitary ulcer syndrome* is a misnomer because multiple small ulcers may be present, or the colon may not be grossly ulcerated at all. Although the syndrome is typically seen in young adults, it may occur at any age. Patients commonly complain of rectal bleeding, rectal pain, and passage of mucus. At sigmoidoscopy, single or multiple well-demarcated, shallow ulcers may be found on the anterolateral or anterior wall of the distal half of the rectum.²¹⁴ An ulcer may not be visible; rather, the mucosa may appear diffusely erythematous, friable, or even polypoid.²¹⁴

Figure 62-23 Rectal varices.
A. Spot radiograph of the distal rectum shows the en face appearance of rectal varices as serpentine folds etched in white (small arrows). In profile, smooth lobulated folds disrupt the contour of the bowel, extending from the anorectal junction proximally (large arrows). **B.** In another patient, spot radiograph of the proximal rectum shows serpentine folds etched in white (short arrows). In profile, a valve of Houston is expanded by a smooth, lobulated submucosal process compatible with a rectal varix (long arrows). (From Rubesin SE, Saul SH, Laufer I, et al: *Carpet lesions of the colon*. *RadioGraphics* 5:537-552, 1985.)

Figure 62-24 Cloacogenic carcinoma. **A.** Lateral spot view of the rectum shows a dominant, large submucosal mass (*large arrows*) indenting the anterior wall of the midrectum. Diffuse infiltration of the remainder of the distal rectum is manifested by smooth narrowing of the distal rectum (*small arrows*). **B.** Supine view of the distal rectum shows diffuse narrowing of the rectal ampulla and a diffusely irregular contour (*arrows*).

Pathologically, the mucosa is mildly inflamed. The glandular epithelium may be hyperplastic, occasionally showing villous formation, which may even be mistaken for villous adenoma.¹¹⁹ The muscularis mucosae is disorganized, and there may be extension of the smooth muscle of the muscularis mucosae into the lamina propria. When mucin-filled glands become cystically dilated, a diagnosis of localized colitis cystica profunda may be made.²¹³ Solitary rectal ulcer syndrome and colitis cystica profunda have been confused with villous adenoma or infiltrating adenocarcinoma. However, the glandular epithelium is not dysplastic in solitary rectal ulcer syndrome and colitis cystica profunda.

The radiographic findings are variable.²¹⁵ The rectal mucosa may appear normal in up to 50% of cases.²¹⁶ Diffuse, finely nodular mucosa in the distal rectum may be seen, correlating with the friable erythematous mucosa seen at proctoscopy (Fig. 62-26). A focal small ulcer may be found on the anterior or anterolateral wall. Redundant prolapsing mucosa may appear as a polypoid mass. Localized colitis cystica profunda may have the appearance of a submucosal mass (Fig. 62-27). The valves of Houston may be markedly enlarged with a nodular contour. Rarely, a stricture may be seen.

Functional Disorders of the Colon

IRRITABLE BOWEL SYNDROME

Epidemiology

Irritable bowel syndrome (IBS) is one of the most common yet least understood conditions encountered in clinical practice. It

is characterized by altered bowel habits and abdominal pain in the absence of detectable structural abnormalities. It occurs with surprising frequency in the general population, as high as 14% in one series, and accounts for one third to one half of outpatient referrals to gastroenterologists.²¹⁷ IBS ranks close to the common cold as a leading cause of absenteeism from work because of illness.²¹⁸ The symptoms of IBS begin before the age of 35 years in 50% of patients, and 40% of patients are 35 to 50 years of age. Female patients outnumber male patients 2:1, and the disease is more common in white and Jewish populations than in persons of color.²¹⁹

Clinical Findings

The clinical findings in irritable syndrome include the following:

1. Abdominal pain relieved by defecation or associated with a change in frequency or consistency of stool
2. Disturbed defecation associated with two more of the following: altered stool frequency, altered stool form (loose and watery or hard), and altered stool passage (straining or urgency, feeling of incomplete evacuation, passage of mucus)
3. Bloating or feeling of abdominal distention

Between 25% and 50% of IBS patients complain of dyspepsia, nausea and vomiting, and heartburn, suggesting that a portion of the gut other than the colon may be involved.²¹⁹

Pathophysiology

Although extensive clinical and laboratory investigations have failed to discover any microbiologic, histologic, or biochemical

Figure 62-25 Cloacogenic carcinoma. **A.** Lateral view of the rectum demonstrates the infiltrative pattern of cloacogenic carcinoma. The anterior wall of the rectum is moderately flattened and lobulated (*short arrows*), and thick nodular folds cross the rectum (*long arrows*). The rectal mucosa is relatively smooth. Focal circumferential extension of tumor around the rectum is seen as flattening of the posterior rectal wall (*open arrow*). **B.** Prone view of the rectum shows mild inbowing and irregularity of the contour of the lateral walls of the rectum (*long arrows*) and thick nodular folds en face (*short arrows*).

abnormalities in patients with IBS, evidence suggests that this disorder is caused by abnormal myoelectric and motor activities in the gut. The myoelectric rhythm of the colon in normal patients has a frequency of 6 cycles/min; most patients with IBS have a predominant frequency of 3 cycles/min. Patients with IBS also have an abnormal gastrocolic reflex, such that the postprandial increase in colonic spike activity and intraluminal pressure is delayed by 30 to 60 minutes. Patients with IBS have a lower threshold for pain and for induction of spastic colonic contraction during rectal distention. It is postulated that this abnormal response is mediated through the autonomic nervous system, as in patients with diffuse esophageal spasm. This exaggerated motor response to colonic distention may explain why patients with spastic colons have symptoms when even small amounts of gas or stool are present.²¹⁷

Recordings of small bowel motility in ambulatory patients with IBS show a high incidence of abnormal activity during waking hours. There are frequent episodes of clustered contractions that occur at 0- to 9-minute intervals, and these are often associated with abdominal pain and discomfort.²¹⁸ Superimposed on these myoelectric abnormalities are environmental factors such as stress and diet, which can also alter motility.

Diagnostic Procedures

IBS is a diagnosis of exclusion, and there is always a nagging fear about missing an organic lesion. In the young patient, inflammatory bowel disease is the primary concern. In patients older than 40 years, the risk of occult colon cancer is such that complete evaluation of the colon by CT colonography, double-contrast barium enema, or colonoscopy is indicated.

There are no typical features of IBS on barium enema studies, which are usually normal in these patients. Some authors have reported a correlation between exaggerated haustral markings and scybalous (pellet-like) stool. Regions of hypertonicity and spasm, sigmoid myochosis, and diverticula have also been associated with IBS, but these findings can be present in patients without IBS and absent in patients with classic IBS. Clearly, the role of radiology in IBS is to exclude structural abnormalities such as inflammatory bowel disease, strictures, and cancer.²¹⁹

Therapy

The first step in therapy of IBS is to reassure the patient and explain the functional nature of this disorder. Foods that can cause symptoms (e.g., caffeine) are eliminated from the diet. Artificial sweeteners, legumes, carbonated beverages, and foods

Figure 62-26 Solitary rectal ulcer syndrome: solitary ulcer. An irregular barium collection (open arrow) 1 cm in diameter is surrounded by a radiolucent halo of edema. Also note mild granularity of the distal rectal mucosa and focal submucosal mass effect (solid arrow).

of the cabbage family are proscribed. Dietary fiber and bulking agents are given because they have been shown to lower pressure in the sigmoid colon. Antispasmodic agents such as tincture of belladonna and dicyclomine (Bentyl) are also helpful. When diarrhea is the presenting symptom, antidiarrheal agents such as loperamide (Imodium) can be used during periods of stress.

CHRONIC CONSTIPATION

Most patients with chronic constipation respond to simple dietary and, if necessary, medical therapy consisting of natural bulk-forming laxatives and stool softeners.^{220,221} Anatomic disorders must be ruled out by colonoscopy, CT colonography, or double-contrast barium enema; metabolic, endocrine, drug-induced, and neurologic causes must be excluded by careful history, physical, and laboratory examinations. Functional evaluation of the colon and anorectum is generally reserved for patients who do not respond to initial therapy and express continued dissatisfaction with their bowel movements.²²¹ The causes of constipation are listed in Boxes 62-2 and 62-3.

Colorectal Transit Studies

The transit of stool through the colon is evaluated by following the progression of swallowed radiopaque markers on radiographs over several days. Patients ingest 20 small radiopaque

Figure 62-27 Solitary rectal ulcer syndrome: colitis cystica profunda. Two smooth-surfaced, polypoid, submucosal-appearing masses (arrows) are seen in the distal rectum. These masses were caused by mucus-filled, epithelium-lined cysts in the submucosa (colitis cystica profunda). (From Levine MS, Piccoletto M, Sollenberger LC, et al: Solitary rectal ulcer syndrome: A radiologic diagnosis? *Gastrointest Radiol* 11:187-193, 1986.)

markers with breakfast food. These markers (Sitzmarks) are commercially available. Abdominal radiographs are taken at 24-hour intervals until all the markers are evacuated or until 7 days pass. If markers are still present, films are obtained at days 10 and 15 to reduce the radiation received by the patient.²²¹

The large bowel is divided into three segments (the right colon, left colon, and rectosigmoid) by the spinous process, and imaginary lines are drawn from L5 to the left iliac crest and pelvic outlet (Fig. 62-28). Sample transit time studies are illustrated in Figure 62-29.

With this test, colonic inertia can be distinguished from normal transit with outlet obstruction. In the latter case, anorectal manometry and defecography are then required. Surprisingly, many studies are normal, and many of these patients have major psychologic factors influencing their symptoms.

Anorectal Manometry

Anorectal manometry is performed to characterize sensory and motor function of the gut, such as rectal sensation and viscoelasticity. Rectal distention produced by a rectal balloon normally initiates a reflex that contracts the external anal sphincter and relaxes the internal anal sphincter. Loss of this reflex suggests Hirschsprung's disease, which must be confirmed by biopsy. Severe idiopathic constipation is usually accompanied by impaired rectal sensation to balloon distention. Paradoxical contraction of the external sphincter and pool relaxation of the internal sphincter during defecation are often associated with constipation. An overall compliant rectum in combination with sensory loss may interfere with the normal urge to defecate.²²⁰

Figure 62-28 Colon transit study. Plain film demonstrates radiopaque markers. For the purpose of counting, the colon is divided into three segments—left colon, right colon, and rectosigmoid.

Evacuation Proctography

Evacuation proctography (defecography) permits dynamic evaluation of the defecation process. It assesses the anorectal angle and status of the puborectalis sling and can diagnose rectal prolapse, rectal intussusception, rectoceles, obstructive enteroceles, and abnormal perineal descent. This test is especially important if there is manometric or electromyographic evidence of hyperactive rectosigmoid junction, abnormal anorectal motility, or anismus and clinical evidence of descending perineum syndrome, prolapse, and the solitary rectal ulcer syndrome. Chapter 52 is devoted to a discussion of this procedure.²²²

The combination of transit studies, anorectal manometry, and evacuation proctography can often identify the type and cause of constipation, which greatly assists further therapy.

NONOBSTRUCTIVE MEGACOLON

Chronic constipation may be caused by a mechanical obstruction (e.g., carcinoma, stricture) or may be of functional origin, as in bedridden older patients or those with improper bowel habits. In Chagas' disease, destruction of the colonic myenteric plexuses by the protozoan *Trypanosoma cruzi* causes striking elongation and dilation, especially of the rectosigmoid and descending colon. Acquired nonobstructive megacolon in adults can also be found in patients with severe neurologic or psychologic disorders and in patients with abnormal colonic motility (e.g., myxedema, infiltrative disease, such as amyloidosis and scleroderma, narcotic drugs). Regardless of the underlying cause, plain abdominal radiographs and CT scans demonstrate a tremendously dilated tortuous colon and rectum filled with a large fecal residue.²²³

Figure 62-29 Abnormal colon transit studies. Diagram depicts characteristic transit patterns of 20 radiopaque markers through the colon during an 8-day period in three groups of constipated patients. With normal transit (red circles), the markers disappear rapidly from the colon. With colon inertia (green circles), there is prolonged transit through the right and left colon segments with delayed appearance in the rectosigmoid. With outlet obstruction (triangles), transit is normal in the right and left colon but there is stagnation of the rectosigmoid. (From Wald A: Colonic transit and anorectal manometry in chronic idiopathic constipation. *Arch Intern Med* 146:1713-1716, 1986.)

Incomplete evacuation of feces over a prolonged period can result in the formation of a fecal impaction—a large, firm, immovable mass of stool in the rectum that may cause large bowel obstruction. Fecal impactions most commonly develop in older, debilitated, or sedentary persons. They can occur in patients who have been inactive for long periods (e.g., because of myocardial infarction, traction), narcotic addicts, patients on large doses of tranquilizers, and children with megacolon or psychologic problems.²²⁴

The symptoms of fecal impaction usually consist of vague rectal fullness and nonspecific abdominal discomfort. A common complaint is overflow diarrhea, the uncontrolled passage of small amounts of watery and semiformal stool around a large obstructing impaction. In bedridden older patients, it is essential that this overflow phenomenon be recognized as secondary to fecal impaction rather than perceived as true diarrhea.

Intestinal myopathy patients have aperistalsis of the esophagus with low pressure of the lower esophageal sphincter, a variable degree of dilation and dysmotility of the stomach, duodenum, small bowel, and colon, and ureteral and bladder enlargement.²²⁵⁻²²⁷

COLLAGEN VASCULAR DISORDERS

Colonic involvement in scleroderma occurs less frequently than is observed in the esophagus and small bowel. Patchy smooth muscle atrophy and fibrotic replacement cause wide-mouthed diverticula at the weakened sites. These are true diverticula that contain all three layers of bowel wall. The smooth muscle is replaced by connective tissue, however. These smooth and wide diverticula retain barium on the postevacuation films.²²⁶

The normal postprandial gastrocolic reflex is decreased in scleroderma patients. This colonic dysmotility may be clinically latent early in disease and manifest only with further smooth muscle atrophy. Similarly, manometric studies have shown decreased pressure of the smooth muscle internal anal sphincter and abnormal relaxation after rectal distention. The external anal sphincter, which is skeletal muscle, responds appropriately. Manometric studies have shown a correlation between the relaxation of the lower esophageal sphincter and dysfunction of the internal anal sphincter in patients with scleroderma. Symptoms from colonic involvement are nonspecific, but decreased motility causes constipation and may result in impaction of fecal contents.²²⁸

Benign pneumoperitoneum can be seen in patients with scleroderma and may be asymptomatic for years. The cause is probably slow passage of bowel gas through minute or microperforations in colonic or small bowel sacculations. Clinically symptomatic and significant bowel perforations may occur in scleroderma from stercoral ulcerations, bowel impactions, and focal vasculitis. These usually require surgical intervention. It may not be possible to differentiate clinically benign pneumoperitoneum from that caused by perforation.²²⁸

Systemic lupus erythematosus can cause a variety of abdominal problems—peritoneal serositis, pancreatitis, ascites, and enteritis. There is a small vessel arteritis of the small bowel and colon that causes ischemia, which leads to edema, hemorrhage, mucosal ulceration, and, ultimately, necrosis and perforation. The radiologic findings are those expected with hemorrhage and ischemia—ileus, thumbprinting, pneumatosis intestinalis, and pseudo-obstruction. The radiologic findings may be indistinguishable from those of ischemia, hemorrhage, or inflammatory bowel disease. Aspirin and corticosteroids are used in the therapy of lupus, and these drugs often aggravate the underlying GI disease.²²⁶

DIABETES

Constipation is the most common GI symptom of the diabetic patient, and it appears to be directly related to autonomic neuropathy. Only 29% of patients without neuropathy symptoms are constipated. This figure increases to 88% in patients with five symptoms of neuropathy. Constipation typically is intermittent and alternates with diarrhea in almost one third of patients. Fecal impaction may be sufficiently severe to produce mechanical obstruction. This autonomic neuropathy leads to the loss of the postprandial gastrocolic response, similar to that observed in patients with intestinal pseudo-obstruction. This is explained pathophysiologically by the inflammatory changes demonstrated in the autonomic ganglia; the cholinergic postganglionic neurons are intact, with a normally responsive smooth muscle.^{204,226}

Pneumatosis Intestinalis

Gas in the bowel wall (pneumatosis intestinalis) can exist as an isolated entity or in conjunction with a broad spectrum of disease of the GI tract or respiratory system. In primary pneumatosis (about 15% of cases), no respiratory or other gastrointestinal abnormality is present. Primary pneumatosis usually occurs in adults and involves mainly the colon. Secondary pneumatosis intestinalis (about 85% of cases) more commonly affects the small bowel and is associated with a wide variety of preexisting disorders. In the primary form, gas collections usually appear cystic; in the secondary type, a linear distribution of gas is generally seen.²²⁹

PRIMARY INTESTINALIS

Primary pneumatosis intestinalis is a relatively rare benign condition characterized pathologically by multiple thin-walled, noncommunicating, gas-filled cysts in the subserosal or submucosal layer of the bowel. The overlying mucosa is entirely normal, as is the muscularis. The appearance of radiolucent clusters of cysts along the contours of the bowel is diagnostic of primary pneumatosis intestinalis. On barium examinations, the filling defects are seen to lie between the lumen (outlined by contrast material) and the water density of the outer wall of the bowel.

The radiographic pattern of pneumatosis can simulate that of more severe GI conditions. Small cysts may be confused with tiny polyps. Larger cysts can produce scalloped defects simulating inflammatory pseudopolyps or the thumbprinting seen with intramural hemorrhage. At times, the cysts of pneumatosis intestinalis concentrically compress the lumen, producing gas shadows that extend on either side of the bowel contour, surrounding a thin, irregular stream of barium and simulating the appearance of an annular carcinoma. To differentiate pneumatosis intestinalis from these other conditions, it is important to note the striking lucency of the gas-filled cysts in contrast to the soft tissue density of an intraluminal or intramural lesion. Other distinguishing factors are the compressibility of the cysts on palpation and the not infrequent occurrence of asymptomatic pneumoperitoneum. Primary pneumatosis intestinalis (Fig. 62-30) usually requires no treatment and resolves spontaneously.²²⁹

SECONDARY INTESTINALIS

Secondary pneumatosis intestinalis usually reflects GI disease with bowel necrosis. In infants, pneumatosis intestinalis suggests an underlying necrotizing enterocolitis, which occurs primarily in premature or debilitated infants, usually affects the ileum and right colon, and has a very low survival rate. This condition is characterized by a frothy or bubbly appearance of gas in the wall of the diseased bowel loops. The appearance often resembles fecal material in the right colon. However, it must be remembered that although this feces-like appearance is normal in adults, it is always abnormal in premature infants. The gas in the wall of the colon in necrotizing enterocolitis is probably related to mucosal necrosis and subsequent passage of intraluminal gas into the bowel wall. This may be complicated by intraluminal gas-forming organisms that also penetrate the diseased mucosa to reach the inner layers of the intestinal wall. Dissection of air into the

Figure 62-30 Primary pneumatosis cystoides intestinalis. **A.** Coronal reformatted image from a CT colonography study in an asymptomatic outpatient shows multiple intramural cystic lucencies. **B.** Axial imaging in another asymptomatic patient demonstrates multiple large gas-filled cysts (arrows), which produced scalloped defects in the transverse colon.

Figure 62-31 Secondary pneumatosis intestinalis. **A.** Coronal reformatted image in a patient with bowel ischemia shows linear intramural lucencies in the right colon. Gas is seen within the mesenteric vessels (arrow) as well. **B.** Linear pneumatosis (arrow) is seen in the ascending colon in this relatively asymptomatic patient undergoing targeted therapy with imatinib for a gastric gastrointestinal stromal tumor.

intrahepatic branches of the portal vein is an ominous prognostic finding.²³⁰

In adults, secondary pneumatosis intestinalis (Fig. 62-31) suggests bowel necrosis caused by mesenteric arterial or venous thrombosis. Secondary pneumatosis intestinalis may be related to mucosal ischemia, as in strangulating obstructions, or to mucosal destruction by infectious organisms or powerful corrosive agents.

Secondary pneumatosis intestinalis may also develop in the absence of necrosis of the bowel wall. Any lesion of the GI tract that results in mucosal ulceration or intestinal obstruction (obstructive bowel disease) can cause secondary pneumatosis intestinalis. Gas in the bowel wall is an uncommon complication of GI endoscopy. Severe obstructive pulmonary disease can also be associated with the development of pneumatosis intestinalis. Partial bronchial obstruction and coughing presumably cause alveolar rupture, with gas dissecting along peribronchial and perivascular tissue planes into the mediastinum. Gas then enters the retroperitoneal area via the

hiatus of the esophagus and aorta, from which it dissects between the leaves of the mesentery to eventually reach subserosal and submucosal locations in the bowel wall.^{231,232}

Patients undergoing molecular targeted therapy with agents such as imatinib, sunitinib, bevacizumab, sorafenib, cetuximab, and erlotinib may develop pneumatosis, perforation, and fistula formation. These patients may be relatively asymptomatic, with these complications found during routine cancer follow-up imaging. Most patients with these therapy-associated intestinal complications can be treated conservatively after discontinuation of molecular targeted therapy.^{231,232}

Other Colon Abnormalities

DIVERSION COLITIS

Diversion colitis is a nonspecific inflammation in a segment of colon that has been surgically isolated from the fecal stream by placement of a proximal colostomy or ileostomy. It is unknown

whether lack of contact of the distal colonic segment to feces somehow deprives the colonic mucosa of necessary exposure to enteric bacteria, bacterial by-products, or nutrients. Conversely, it is conceivable that diversion colitis results from stasis within the inactive segment, causing excessive mucosal exposure to unrecognized intraluminal toxins. Radiographically, diversion colitis resembles ulcerative or Crohn's colitis with punctate or aphthoid ulcerations, which may produce a diffuse, granular mucosal appearance in severe or long-standing cases. Isolated inflammatory polyps or diffuse mucosal nodularity may occur.²³³⁻²³⁶

BEHÇET'S SYNDROME

Behçet's syndrome is a systemic inflammatory disease involving a triad of uveitis, oral ulcers, and genital ulcers, as well as involvement of the central nervous system, joints, kidneys, skin, and GI tract. It is unclear whether the cause of this disorder is viral, allergic, environmental, or autoimmune.²³⁷

Abdominal pain occurs in up to 75% of patients, and the clinical course can be complicated by diarrhea, malabsorption, bleeding, perforation, fistulas, and toxic megacolon. Ulcerations tend to involve the terminal ileum, cecum, and ascending colon, simulating Crohn's disease and some infectious colitides. Diffuse colonic involvement can mimic ulcerative colitis.²³⁸

The barium enema appearance of Behçet's disease varies from mild proctitis to pancolitis with multiple discrete ulcers and inflammatory polyposis. Aphthoid ulcerations and skip lesions are typical. The ulcers in Behçet's syndrome tend to be larger and deeper than those in Crohn's colitis, leading to a higher incidence of perforation and hemorrhage.^{239,240}

AMYLOIDOSIS

As in other parts of the bowel, amyloidosis involving the colon can produce a broad spectrum of radiographic abnormalities. Narrowing and rigidity of the colon, especially in the rectum and sigmoid colon, can result from direct deposition of amyloid within the mucosal and muscular layers of the bowel or can be secondary to extensive amyloid deposition in blood vessel walls and subsequent ischemic colitis. The resulting thickening of the bowel with effacement of haustral markings can closely simulate the radiographic appearance of chronic ulcerative colitis. Less commonly, amyloidosis can produce an acute ulcerating process, single or multiple discrete colonic filling defects, or an appearance simulating the thumbprinting seen with ischemic colitis.²⁴¹⁻²⁴⁴

CATHARTIC COLON

Cathartic colon is caused by the prolonged use of stimulant or irritant cathartics (e.g., castor oil, phenolphthalein, cascara, senna, podophyllum). The radiographic appearance of cathartic colon is similar to that of burned-out chronic ulcerative colitis. In contrast to ulcerative colitis, however, the absent or diminished haustral markings, bizarre contractions, and inconstant areas of narrowing primarily involve the right colon (Fig. 62-32). In severe cases, the left side of the colon can also be affected, although the sigmoid colon and rectum usually appear normal. The mucosal pattern is linear or smooth; ulcerations are not seen. The ileocecal valve is frequently flattened and gaping, simulating the backwash ileitis seen in ulcerative colitis.

Figure 62-32 Cathartic colon. Contractions with irregular areas of narrowing are seen in the right colon, and there is a paucity of haustra in the transverse colon.

Shortening of the ascending colon can be severe but, unlike the rigidity of the tubular bowel in chronic ulcerative colitis, the shortened segment in a cathartic colon remains remarkably distensible. Inconstant areas of narrowing of the bowel lumen can be seen at fluoroscopy and on radiographs of patients with cathartic colon. These pseudostrictures primarily involve the hepatic flexure, vary in length, have a concentric lumen with tapering margins, and often disappear during a single examination.²⁴⁵⁻²⁴⁷

URTICARIA

A characteristic mucosal pattern of large, round or polygonal, raised plaques in a grossly dilated bowel was first described as an allergic reaction of the colonic mucosa to medication. This so-called colonic urticaria predominantly involves the right colon, can be seen without concomitant cutaneous lesions, and regresses once the offending medication is withdrawn.²⁴⁸

A pattern similar to colonic urticaria has been reported in several other conditions for which the common denominator seems to be submucosal edema. In herpes zoster, an exanthematous neurocutaneous disorder secondary to reactivation or reinfection by a large poxvirus, colonic mucosal blebs infrequently appear as multiple small, discrete, polygonal filling defects, with sharp angular margins (Fig. 62-33). These blebs correspond morphologically and temporarily to the vesicular phase of the cutaneous lesion and are segmentally arrayed in a corresponding or noncorresponding dermatome. In *Yersinia* colitis, submucosal edema is caused by an alteration in vascular permeability. A similar radiographic pattern has also been observed in patients with submucosal colonic edema secondary

to obstructing carcinoma, cecal volvulus, ischemia, colonic ileus, and benign colonic obstruction.²⁴⁹

COLITIS CYSTICA PROFUNDA

Colitis cystica profunda is a rare benign disease in which large, mucous epithelium-lined cysts up to 2 cm in diameter form in the submucosal layer of the colon. These cysts are usually seen in the rectum and pelvic colon, and usually only a short segment of colon is involved. Colitis cystica profunda is associated with solitary rectal ulcer syndrome and rectal prolapse, as well as other proctitides. This suggests that these cysts are formed when surface mucosa is implanted into the colonic submucosa during the healing phase of an ulcerative inflammatory process. Because these cells cannot be shed into the lumen and mucus cannot be discharged, a cystic mass develops.^{250,251}

Patients with colitis cystica profunda present with hematochezia, passage of mucus or pus per rectum, diarrhea, constipation, tenesmus, and rectal, sacral, or abdominal pain. On barium studies, multiple, irregular, rectal filling defects suggesting adenomatous polyps are seen. Barium filling clefts between these polyps can simulate mucosal ulcerations. Ischemic colitis can be mimicked when sufficient scalloping of the colon occurs.^{252,253}

As with solitary rectal ulcer syndrome, conservative treatment is the initial approach. Surgery to correct rectal prolapse may lead to resolution of cysts in certain patients

Figure 62-33 Colonic urticaria. Raised polygonal plaques are present in the ascending colon in this patient with *Yersinia* colitis.

with refractory symptoms and rectal prolapse evident on defecography.²⁵⁴⁻²⁵⁶

DIARRHEA

In Western countries, most cases of diarrhea are self-limited (Box 62-4) and seldom come to radiologic attention. When the diarrhea persists (Box 62-5), radiology plays an important part in diagnosis. Radiologic findings, however, must be interpreted in view of clinical and laboratory findings. There are three fundamental types of diarrhea—osmotic, secretory, and inflammatory.

Osmotic Diarrhea

Osmotic diarrhea usually occurs as a result of malabsorption or ingestion of certain chemicals in which a high osmotic load is presented to the gut. Small bowel series and enteroclysis are superb means of demonstrating causes of malabsorption, such as sprue, amyloidosis, mastocytosis, intestinal lymphangiectasia, intestinal anastomoses, small bowel diverticula, and abnormal motility, which predispose to bacterial overgrowth. Chronic

*(>4-wk duration).

pancreatitis, cystic fibrosis, the Shwachman-Diamond syndrome, and other causes of pancreatic insufficiency have characteristic appearances on imaging studies that can specifically establish the cause of the diarrhea.²⁵⁷

Secretory Diarrhea

Secretory diarrhea stimulates intestinal secretion or inhibits absorption. Enterotoxins produced by certain infections, certain irritant laxatives, metals, and toxins, and tumors that elaborate secretagogues, such as vasoactive intestinal polypeptide (pancreatic cholera), are major causative factors in

secretory diarrheas. Radiology has only a small role in the assessment of these patients unless the diarrhea is caused by a pancreatic tumor.²⁵⁸

Inflammatory Diarrhea

Radiology is most useful for evaluating inflammatory diarrhea, in which inflammatory damage and death of the brush border and epithelium occur. This diarrhea occurs in patients with inflammatory bowel disease, certain infections, and radiation enteritis and as a complication of chemotherapy and graft-versus-host disease.^{259,260}

Ileal Pouch–Anal Anastomosis

Colonic Stents

Radiologists are often asked to evaluate the postoperative colon to exclude complications such as fistula, dehiscence, stricture, and abscess formation. Radiologists are also called on to assess the colon in the asymptomatic patient for anastomotic healing or resolution of inflammatory disease before a colostomy is closed. The radiologist must be familiar with the details of the surgical procedure, terminology, and individual surgeon's modifications to render an intelligent consultation. The major surgical procedures performed on the colon are discussed in this chapter. Although there is increasing use of the laparoscopic approach to colonic surgeries, the structural end results are similar to those of their open counterparts. The minute intraoperative technical details have been well described in classic surgical textbooks.¹⁻⁴

Segmental Resection

Segmental resection entails surgical removal of a diseased segment of the colon. Colonic continuity is usually restored with an end-to-end colocolic or ileocolic anastomosis (Figs. 63-1 and 63-2). The latter is created for patients who undergo resection of the cecum or right colon. In some patients, the anastomotic line may be seen as a short-segment, ringlike indentation during contrast examination of the colon (Fig. 63-3), but in many patients the site of the anastomosis may not be discernible unless defined by surgical staples. Currently, most

surgeons use stapling devices rather than traditional hand-sewn anastomoses to reestablish bowel continuity. The stapling units usually create a uniform ring of staples. Disruption of the ring on a plain film of the abdomen may indicate disruption of the anastomosis. A segmental resection may be performed in conjunction with an upstream diverting ileostomy or colostomy (see later).

Prior to colostomy takedown, the surgeon may request a preoperative examination of the anastomosis to ensure integrity. In terms of technique, the examination is performed after placement of a rectal tube or Foley catheter into the rectum, with instillation of water-soluble contrast material under fluoroscopy. The examination should focus on the region of the anastomosis, with imaging performed in multiple projections and with the patient in a variety of positions. In particular, the examination should be performed with a mild degree of stress to the anastomosis. For example, rather than performing an examination of a sigmoid anastomosis entirely in the recumbent position, a high-pressure view of the sigmoid in a right posterior oblique and/or reverse Trendelenburg position should be performed. This will create a column of contrast at the level of the anastomosis, potentially revealing a leak that could be missed if the contrast flowed past the anastomosis in a low-pressure position (left posterior oblique and Trendelenburg position).

Side-to-Side Enterocolic Anastomosis

A side-to-side enterocolic anastomosis (Fig. 63-4) may be created when a diseased segment of distal small bowel (as in Crohn's disease or radiation enteritis) is bypassed or when the length of the functional small bowel is shortened for treatment of morbid obesity. Currently, this procedure is rarely performed in isolation. Surgeons prefer to resect rather than bypass small bowel involved by Crohn's disease. Gastric restrictive surgeries, including gastric stapling and Roux-en-Y gastric bypass, are much preferred over a small bowel bypass procedure as therapy for morbid obesity (see Chapter 35).

Colostomy

A colostomy is a colcutaneous opening, or stoma, created to decompress a colonic obstruction or divert the fecal stream away from the distal colon. Diverting colostomies may be performed to protect a distal anastomosis that has recently been created and requires time to heal or to direct the fecal stream away from a segment of distal colon that is too inflamed to be resected at the time of the initial operation. If the surgeon elects to resect the diseased segment, he or she may choose to perform an end-to-end anastomosis and divert the fecal stream with a temporary colostomy. The colon proximal to the stoma is often evaluated radiographically to rule out

Figure 63-1 Segmental sigmoid resection and end-to-end colocolic anastomosis. Foreshortening of the sigmoid colon may or may not be apparent radiographically, depending on the length of colon resected.

Figure 63-2 Ileal-transverse colonic anastomosis. The small bowel proximal to the anastomosis (*long arrow*) has an abnormal appearance with pseudohaustra (*short arrows*) and dilation, an appearance known as *colonization*.

Figure 63-3 Postoperative deformity after closure of prior diverting colostomy. A prominent short-segment annular constriction (*arrow*) is present in the transverse colon with intact mucosa. Serosal metastatic disease can have the same appearance.

Figure 63-4 Side-to-side enterocolic anastomosis. Evaluation of the colon proximal to the anastomosis may be technically difficult because of preferential filling of the distal small bowel.

additional colonic lesions, whereas the distal colon is evaluated to assess the status of a distal anastomosis or a previously inflamed segment.

Stomal creation is associated with a number of complications. Necrosis may occur if the blood supply is compromised by tension or compression during formation of the stoma. The stoma may become detached from the abdominal wall and migrate into the abdominal cavity. With stomal recession, it may remain attached to the abdominal wall but retract into the abdomen, causing inflammation of the surrounding skin. The bowel may also prolapse or intussuscept through the stoma. When they occur, parastomal hernias may contain small or, rarely, large bowel that passes through an enlarged fascial defect adjacent to the stoma. The hernia may remain in the subcutaneous tissues (Fig. 63-5) or may protrude externally beside the stoma. In obese patients, these hernias can be difficult to detect clinically but are readily apparent on abdominal computed tomography (CT) scans. Parastomal hernias can result in bowel obstructions and can be difficult for the surgeon to repair. Parastomal hernias causing stomal obstruction or dysfunction may be intermittent. When examining a stoma at fluoroscopy, tangential views should be obtained with and without a Valsalva maneuver to elicit bowel herniation into a parastomal hernia. Stomal ulceration may occur because of mechanical irritation from the stomal appliance. The choice of colostomy depends on whether it is to be permanent or temporary, the patient's body habitus, previous operations, and the surgeon's preference.

END-COLOSTOMY

An end-colostomy may be performed as a definitive procedure in patients with distal rectal carcinoma or as part of a two-stage procedure for diverticulitis. The stoma is usually in the left lower quadrant, and the descending colon or residual sigmoid colon is the portion that forms the stomal opening. This procedure is often performed in association with the Hartmann

procedure to close off the rectal stump, so only one stoma is present.

LOOP COLOSTOMY

A loop colostomy is usually performed for the following indications: (1) as a temporary procedure to relieve an acute obstruction of the distal colon or to protect a new distal colonic anastomosis; and (2) as a permanent procedure for unresectable advanced lesions. A loop of transverse or sigmoid colon is brought to the surface of the abdominal wall, sutured in place on the outside, and then opened up, creating afferent and efferent stomas. The mucosa connecting the two stomal openings is the posterior wall of the colon. Patients are usually aware of which stoma produces feces and are able to direct the radiologist to examine the correct portion of the colon.

DOUBLE-BARRELED COLOSTOMY

A double-barreled colostomy is created when the colon is divided completely and the two cut ends are sewn side by side to each other, but this type of colostomy is rarely performed. This type of stoma also has two openings, and the patient can usually tell which one is the productive orifice. This procedure is chosen because the stoma can be closed without reentering the abdomen. The apposed common walls are cut, and the stoma closes spontaneously, or the margins of the two stomal openings can be pursed together with minimal suturing under local anesthesia.

DIVIDED COLOSTOMY AND MUCOUS FISTULA

A divided colostomy and mucous fistula operation creates two separate colostomies—one for the proximal colon, creating an efferent or productive stoma, and one for the distal colon, creating an afferent stoma (Fig. 63-6). From the afferent stoma, the

Figure 63-5 Parastomal hernia. Large parastomal hernia (arrows) containing unobstructed small bowel in this patient status total proctocolectomy and end-ileostomy for Crohn's disease.

Figure 63-6 Typical diverting transverse colostomy. This demonstrates a fecal stoma, mucous fistula stoma, and end-to-end sigmoid anastomosis.

Figure 63-7 Rectal deformity caused by prior abscess and drainage. Examination performed because of a family history of colonic carcinoma demonstrates a short, annular constriction (arrows) in the midrectum that was not present on an examination performed 6 years earlier. Endoscopy showed normal mucosa in the contracted segment. Additional history was obtained before ordering further studies. An intervening appendectomy at another institution 4 years earlier required postoperative transrectal drainage of a perirectal abscess. This case represents residual deformity from that abscess and its treatment.

Figure 63-8 Ileal-ascending colonic anastomosis. This procedure is performed after resection of a right colonic tumor or ileocecal Crohn's disease.

colon carries only mucus to the rectum; this stoma has been called a *mucous stoma* or *mucous fistula*. This procedure is not commonly performed but may be chosen to ensure that no fecal debris enters the distal colon.

At 6 to 8 weeks, the colon is usually reexamined before closing the diverting colostomy to ensure that there is no leakage and that regional inflammatory changes have subsided. When the colon is evaluated to exclude a fistula, a single-contrast rather than a double-contrast barium enema study should be performed. Barium is safe to use in the asymptomatic patient because extravasation, when it occurs, has a well-formed sinus tract, and barium does not enter the peritoneal cavity. Also, barium has contrast characteristics superior to those of water-soluble contrast agents, which may not be sufficiently dense and can become diluted in such a tract, making it difficult to visualize tiny tracts during fluoroscopy of organs low in the bony pelvis.

After diversion of the fecal stream with a colostomy, the distal colon may have an abnormal appearance when examined before closure. The unused segment of the colon may appear nondistensible and may have an abnormal mucosal pattern, with nodularity and lymphoid follicular hyperplasia.⁵ This condition is known as *diversion colitis*. The apparent absence of distensibility is probably the result of chronic lack of distention, and the mucosal irregularity is likely secondary to adherent mucus in a contracted and unprepared colon. Patients may be asymptomatic; this entity likely represents a radiographic phenomenon rather than a true colitis. With restoration of the fecal stream after closure of the colostomy, the morphologic features of the colon return to normal unless underlying colonic inflammatory disease is present. A deformity may be created at the site of the previous colostomy and may cause radiographic confusion when the history is not correlated with the radiographic examination. The appearance is variable and may resemble that of a polypoid filling defect, smooth or nodular annular lesion, or submucosal or serosal process (see Fig. 63-3). Any colonic operative or endoscopic procedure may also produce a persistent deformity that can mimic disease (Fig. 63-7). Careful review of the patient's history should prevent a misdiagnosis.

Cecostomy

Cecostomy is a surgical procedure in which an opening is created in the cecum to relieve cecal distention produced by intestinal pseudo-obstruction, profound paralytic ileus, or, rarely, distal obstruction (e.g., tumor, cecal volvulus). It is a temporizing or palliative measure in acutely ill patients and in those who would not tolerate a definitive but more prolonged right hemicolectomy and ileal ascending colonic anastomosis (Fig. 63-8) or resection of a distal colonic obstructive process. A tube is placed in the cecum and brought to the abdominal surface to relieve colonic distention. A cecostomy may be performed by the surgeon, interventional radiologist, or gastroenterologist. A definitive surgical procedure can later be performed when the patient's condition permits.

Low Anterior Resection

Low anterior resection, performed for carcinoma of the proximal rectum and midrectum, entails resection of the rectosigmoid and anastomosis of a cuff of the proximal colon to the distal rectum below the peritoneal reflection. It involves an

anastomosis deep within the pelvis and may be difficult to perform. The surgeon must determine how low a resection to perform; this decision depends on the patient's body habitus, nature of the lesion to be resected, and skill of the surgeon. Depending on the amount of residual rectum, a straight colorectal anastomosis or pouch to rectal anastomosis may be performed (see later, "Proctectomy and Coloanal Anastomoses"). Stapling devices greatly facilitate the technical performance of low anterior resection. A temporary, protective diverting ileostomy or colostomy may be created in conjunction with this procedure.

Preoperatively, the surgeon may wish to obtain a proctoscopic measurement or radiographic estimation of the distance from the anal canal to the lesion. Postoperatively, the status of the anastomosis may require evaluation with a water-soluble contrast enema before closure of the ostomy. The examination is performed with a gently placed 12F Foley or small-caliber red rubber catheter that is taped onto the adjacent gluteal skin; inflation of the balloon could disrupt the anastomosis. Leakage from a low anastomosis within the pelvis may produce a pelvic abscess, perirectal abscess, or colovaginal fistula (Fig. 63-9).

Proctectomy and Coloanal Anastomoses

A proctectomy with coloanal anastomosis is a means of removing the rectum while preserving colonic continuity and anal sphincter function. This is performed primarily in patients with rectal carcinoma involving the mid and lower thirds of the rectum. Total mesorectal excision is preformed to reduce the risk of local recurrence. The tumor is excised with a relatively

Figure 63-9 Rectovaginal fistula. Contrast material is identified in the vagina (open arrow). Surgical clips (solid arrow) seen posteriorly define the level of the anastomosis and level of the fistula.

short distal margin while preserving the anal sphincter. Previously, the colon was reattached to the anus via a straight coloanal anastomosis, but the current procedure of choice is the colonic J-pouch anastomosis (Fig. 63-10). This has improved functional outcome over a straight anastomosis, particularly in the first postoperative year.^{6,7} The technique involves folding the distal aspect of the residual colon upon itself and dividing the septum to create a reservoir for fecal material. The pouch is hand-sewn or stapled directly to the anus. A diverting colostomy or ileostomy may also be performed. Similar to other colonic anastomoses, the surgeon may request a water-soluble contrast examination prior to ileostomy takedown (Fig. 63-11).

Figure 63-10 Colon J pouch. A segment of distal colonic is folded upon itself, divided, and anastomosed to the anus, creating a reservoir for fecal material after low anterior resection.

Figure 63-11 Colon J pouch. This is the normal appearance of a colon J pouch on a retrograde water-soluble contrast study performed prior to takedown of a diverting ileostomy.

Figure 63-12 Colon J pouch leak and inflammation. CT scan of the pelvis in a patient status postproctectomy and colon J pouch for a low rectal cancer shows a leak and presacral inflammation at the blind-ending stump of the J pouch (arrowhead) that was not detected prior to ileostomy takedown.

Another surgical technique in patients with difficult anatomy is the coloplasty pouch. This involves a longitudinal incision in the descending colon, which is then closed transversely. This creates a pouch that may be technically easier to anastomose to the anus in patients with a narrow pelvis. Early studies indicated a higher rate of anastomotic leaks, particularly at the distal end of the incision, but improved functional results compared with a straight coloanal anastomosis.^{8,9}

All types of coloanal anastomoses can be complicated by anastomotic leaks and associated abscesses (Fig. 63-12).

Abdominoperineal Resection

Lesions involving the anal sphincter complex usually require an abdominoperineal resection. In this procedure, the rectum and anal sphincter complex are removed via an abdominal and perineal approach, with creation of a permanent colostomy. Major radiologic complications are related to abdominal or pelvic abscesses.¹⁰ Colostomy complications can also arise, similar to those discussed earlier.

Hartmann Procedure

During the Hartmann procedure, a tumor or segment of sigmoid diverticulitis is resected, an end colostomy is created, and the distal rectal stump is closed by stapled sutures or sewn by hand (Fig. 63-13). The resulting Hartmann pouch becomes a blind segment of colon from the anus to the sealed stump. The procedure is used when a primary reanastomosis is thought

Figure 63-13 Closed rectal pouch. This line drawing shows a Hartmann pouch with a terminal ileostomy.

to be unsafe and is usually performed with complicated diverticulitis, but may also be performed for other indications, including colon and rectal cancers, inflammatory bowel disease, and trauma. Bowel continuity can subsequently be reestablished by a colorectal anastomosis. In some patients, however, the surgeon may elect not to reestablish continuity for medical or technical reasons. The blind pouch normally may contain fecal debris, inspissated mucus, or enteroliths. Polyps or carcinoma can also develop in this segment.¹¹ Patients may be asymptomatic until the tumor has become far advanced. Although the classic Hartmann pouch involves only a portion of the rectum, in practice the pouch may be much longer and include part or all of the sigmoid colon. A Hartmann pouch may also be created after total colectomy and creation of an ileostomy for Crohn's disease or ulcerative colitis.

Mucous Fistula

Rather than closing off the rectal stump, a rectosigmoid stoma or mucous fistula may be created by bringing out the proximal cut end of the distal sigmoid colon or rectum, which results in a stoma that produces only mucus. The distal colon extends from the stoma of the mucous fistula distally to the anus.

Appendectomy

Appendectomy is a procedure in which the appendix is tied at its junction with the cecum and is resected. The stump is ligated and inverted. Occasionally, this operation may produce a sizable, smooth polypoid defect at the base of the cecum (Fig. 63-14). A history of appendectomy and the typical location of the defect at the apex of the cecum should help prevent a mistaken diagnosis of cecal polyp. Nodularity, mucosal disruption, or a location away from the cecal apex should arouse suspicion that it is a true polyp requiring colonoscopic evaluation.

Ileal Pouch–Anal Anastomosis

Ileal pouch–anal anastomosis is performed in patients who have ulcerative colitis (see Chapter 57) or familial polyposis (see Chapter 61).^{12,13} It is an alternative to proctocolectomy that offers the potential for nearly normal defecation through an intact anus. Careful radiographic and clinical evaluation of the patient to exclude Crohn's disease is essential. Patients with Crohn's disease may not tolerate extensive pelvic surgery, and perineal fistulas and sinus tracts, inflammation of the pouch, and anastomotic strictures may develop. The procedure consists of colectomy, mucosal proctectomy, and creation of a small bowel reservoir. The colon and most of the rectum are removed, leaving the distal portion of the rectum in place. The mucosa is dissected from this rectal remnant, leaving a cuff of denuded rectum with intact muscularis propria, based on the concept that the intact sensory innervation of this segment enables the patient to sense bowel distention and have the urge to

Figure 63-14 Appendiceal stump deformity. A broad-based defect (arrows) at the apex of the cecum is caused by a previous appendectomy. Most appendectomies produce minimal or no deformity of the cecum.

defecate. Although bowel movements may be increased in frequency, patients may need to defecate no more often than they normally urinate. Some patients have nocturnal soiling, but the quality of life of patients who had ulcerative colitis is greatly enhanced, and the risk of developing colonic carcinoma is eliminated.

The most common pouch is a J pouch, although an S or side-to-side (Fonkalsrud) pouch may be created (Fig. 63-15). The J pouch is formed when the distal ileum is closed and the ileum is doubled on itself, forming a J configuration. The apposed walls of the two limbs are stapled to each other, and the two segments are opened, creating a pouch that has the volume of two limbs (Fig. 63-16). The staples delineate the length of the pouch. The pouch is placed into the rectal cuff, a hole is created at the apex of the pouch, and the pouch is stapled to the anal mucosa.

The S pouch is created by apposing and suturing three limbs of the distal ileum to each other. The common walls are opened, creating a pouch with the diameter of three segments of small bowel. This pouch and the Fonkalsrud pouch have an efferent limb that is brought into the rectal cuff, and its mucosa is sutured to the dentate line of the anal canal.

The Fonkalsrud pouch is created by resecting a segment of the distal ileum. This segment is placed next to another loop of ileum, and a side-to-side anastomosis is created.

The ileal pouch–anal anastomosis procedure is usually performed in two stages. The first stage consists of a total colectomy, creation of the pouch and pouch–anal anastomosis, and creation of a protective diverting ileostomy. The second stage is ileostomy closure, which is performed after a period of 6 to 8 weeks, allowing suture lines to mature. Before closure, the surgeon examines the anorectum. If the anorectum is normal, a barium enema is performed to rule out small leaks from the pouch staple lines or pouch–anal anastomosis. If the clinical examination is abnormal, the barium enema is delayed or CT is performed. Abscesses tend to occur later and are best seen on CT examination.

A three-stage procedure may be required when the patient is weakened by fulminant colitis and is receiving high-dose corticosteroid therapy. The first stage consists of creation of a simple ileostomy, colectomy, and Hartmann closure of the rectum. The second stage is performed several months later, when healing and recovery of electrolyte and endocrine integrity have occurred (usually after corticosteroid withdrawal). The remainder of the rectum is resected, mucosal proctectomy is performed, and a pouch with pouch–anal anastomosis is created. The third stage is closure of the ileostomy 6 to 8 weeks later.

Figure 63-15 Three major types of ileal pouch–anal anastomosis. A. J pouch. B. S pouch. C. Side-to-side (Fonkalsrud) pouch.

Figure 63-16 Normal J-pouch reservoir before closure of the diverting ileostomy. Note the long J-pouch appendage (top solid arrow) and the efferent limb (open arrow) leading from the ileostomy to the pouch. In this supine oblique view, air is present (bottom solid arrow) in the anterior portion of the pouch at the pouch–anal anastomotic region. Contrast material should be positioned at the pouch–anal anastomosis by placing the patient in a 45-degree erect position or turning the patient toward the prone position until air is displaced by contrast material.

Any of the complications that attend all major abdominal operations may develop after ileal pouch–anal anastomosis, including abscesses, ileus, or small bowel obstruction.^{14,15} The small bowel mesentery limits mobility of the ileum, and the small bowel may have to be manipulated extensively to create the ileal pouch–anal anastomosis. This manipulation may contribute to the prolonged ileus seen in some patients. Small bowel obstruction may develop in the immediate postoperative period, in the period between creation of the pouch and closure of the ileostomy, or at any time during the remainder of the patient's life. A mesenteric hematoma may occur if small mesenteric vessels rupture because of manipulation of or prolonged tension on the mesentery. The superior mesenteric artery syndrome can develop if tension placed on the mesentery in an attempt to position the pouch in the lowest portion of the pelvis retracts the superior mesenteric artery against the aorta.^{15,16} Prophylactic release of the small bowel mesentery at the ligament of Treitz, mesenteric lengthening incisions, and judicious suturing and resection of stretched branch mesenteric vessels facilitate mobilization of the terminal ileal pouch into the pelvis.¹⁷

Although leakage may occur from the suture lines of the pouch (Fig. 63-17), this complication usually occurs at the ileal

Figure 63-17 Pouch leak. Leakage (arrow) from a J-pouch reservoir with a presacral fistula and collection.

pouch–anal anastomosis (Figs. 63-18 and 63-19). Anteroposterior, oblique, and lateral views of the distended, gas-free pouch in a 30- to 45-degree upright position must be obtained low enough to include the ileal pouch–anal canal junction. CT scans may also depict pouch leaks (Fig. 63-20). Leakage from the pouch or from the ileal pouch–anal anastomosis requires that closure of the diverting ileostomy be postponed until healing of the leak has been confirmed. Small leaks and collections may be treated by endoscopic drainage, suturing, or antibiotic therapy if they do not resolve spontaneously.¹⁸ A small length of closed reflected ileum often is not incorporated into the J pouch, termed the *J-pouch appendage* (Fig. 63-21; see also Fig. 63-16). This appendage may leak, may be long enough to twist and necrose, or may simulate leakage (see Fig. 63-21).¹⁹ The S pouch and Fonkalsrud pouch have efferent limbs that pass from the pouch to the anus. These pouches, when distended with fecal contents, may compress the efferent limb and interfere with pouch emptying. Some patients with this condition succeed in emptying their pouch by self-catheterization.

Patients who tolerate the complete procedure may return with so-called pouchitis, complaining of tenesmus and diarrhea and, rarely, with bleeding, fever, arthralgias, and other systemic symptoms.^{20,21} Endoscopic examination of the pouch may reveal redness and ulceration.²² Pouchitis is not associated with consistent radiographic findings, and its cause is unknown.

With time, accommodation of the small bowel to the pouch leads to an increased capacity and small bowel dilation, which can simulate small bowel obstruction on abdominal radiographs. When clinical and radiographic findings are confusing,

Figure 63-18 Pouch leak. Leakage from the J-pouch–anal anastomosis of a J-pouch reservoir is seen. Leakage from any anal anastomosis has a typical chevron appearance resulting from tracking of the extravasated contrast material between the rectal cuff and the pouch or efferent limb inserted into the cuff. (From Kremers PW, Scholz FJ, Schoetz DJ Jr, et al: *Radiology of the ileoanal reservoir*. AJR 145:559–567, 1985.)

Figure 63-20 CT scan of pouch leak. CT scan with oral and IV contrast depicts a leak (arrows) at the pouch–anal anastomosis on this coronal reformatted image.

Figure 63-19 Chevron configuration of ileoanal anastomotic leak. Diagrammatic illustration of the mechanism of extravasation from a pouch–anal anastomosis. *Right*, Mucus (or contrast material) passes from the point of disruption (short curved arrow) and courses between the cuff and the cuff of rectum, producing the chevron configuration seen in [Figure 63-18](#). Purulent material eventually dissects beyond the cuff and spills (long curved arrow) into the perirectal soft tissues. (From Kremers PW, Scholz FJ, Schoetz DJ Jr, et al: *Radiology of the ileoanal reservoir*. AJR 145:559–567, 1985.)

Figure 63-21 Pseudoleakage. This appearance is commonly seen with a J-pouch reservoir in which there is incomplete filling of the J-pouch appendage and represents a potential radiographic pitfall. **A.** Traces of contrast material (arrows) appear to extravasate from the proximal posterior part of the J-pouch reservoir. **B.** Additional spot image with further distention shows contrast material surrounded by a faintly visible suture line (arrows) just anterior to the sacrum. The lateral view also demonstrates the anterior position of the lower portion of the pouch, which traps air in the supine position, impairing visualization of the J pouch–anal anastomosis. (From Kremers PW, Scholz FJ, Schoetz DJ Jr, et al: *Radiology of the ileoanal reservoir*. AJR 145:559–567, 1985.)

Figure 63-22 Colonic stent. **A.** Normal appearance of stent with central waistlike narrowing. **B.** Recurrent large bowel obstruction with migrated colonic stent currently located in distal rectum. Note the absence of waistlike narrowing.

enteroclysis or retrograde small bowel enema examination may be required to rule out mechanical obstruction.

Occasionally, patients post–pouch procedure for ulcerative colitis return years later with symptoms and are found by radiography to have small bowel Crohn's disease. Further review of the original pathology may show sparse granulomas in the colon.

Colonic Stents

Colonic stents are sometimes placed for treatment of large bowel obstruction.^{23,24} These procedures are usually palliative and are

performed in patients with colon cancer or obstructing colonic metastases whose condition is deemed unresectable or who are unable to tolerate definitive resection. On occasion, stents are a temporal bridge to definitive colonic resection, avoiding emergency surgery. Obstructing lesions are traversed with a guide wire, and metallic stents are deployed to relieve the obstruction. Postprocedural radiographs demonstrate waistlike midstent narrowing that indicates satisfactory placement across the stricture (Fig. 63-22A). The most common complications of colon stent placement seen on radiographic studies include perforation, stent migration (Fig. 63-22B), and recurrent obstruction.²⁵

Historical Perspective

The practice of medicine has been transformed by computed tomography (CT). In recognition of the importance of this technique, Cormack and Hounsfield were awarded the Nobel Prize in 1979 for their role in its development.¹ The first clinical CT unit was placed at Atkinson Morley Hospital in England on October 1, 1971.¹ Each image took 4 minutes to be acquired, and 2 days were needed to reconstruct the series. The clinical importance of CT was immediately appreciated; by 1976, 22 companies were manufacturing CT scanners, and in 1979, more than 1000 scanners were in use throughout the world. Since then, there has been continuous and dramatic improvement in both spatial and temporal resolution as a result of advances in both hardware and software design, particularly the development of helical and multidetector helical CT and dual-energy CT.

Creating the Computed Tomography Image

The fundamental concept of CT is to use multiple projections of an object to reconstruct the internal structure of that object.^{2,3} The creation of a CT image can be divided into three steps. Data

acquisition involves the actual exposure to radiation (scanning of the patient) with the creation of raw data; image reconstruction involves processing of the raw data into a numerical matrix revealing the internal structure; and image display involves converting the numerical data matrix to a gray-scale image. Each of these is discussed with conventional CT, and then the changes created by the advent of helical and multidetector helical CT are described.

DATA ACQUISITION

An x-ray tube and an opposing array of detectors as well as the associated electronics are mounted on a track or frame called a gantry. The x-ray tube produces a fan-shaped beam of x-rays that interact with the patient by absorption or scattering; some of the x-rays pass through the patient to interact with the detector array. During data acquisition, the tube and detectors rotate around the patient, and the detectors repeatedly measure the amount of x-ray energy transmitted through the patient. The amount of x-ray energy received by the detector and the gantry angle at the time of the measurement are recorded (Fig. 65-1). Typically, the detector array contains 500 to 1000 detectors, each of which is sampled approximately 1000 times per revolution.³ Each line of this information reflects the summation of the attenuation coefficients of all structures in that x-ray path. The entire data set forms the “raw data” from which an image is reconstructed. Conventional or incremental scanning is obtained by performing a series of individual scans during suspended respiration. After each scan, the patient breathes; the table is advanced; and in most machines, the tube and detector apparatus rewinds to begin another scan.⁴

IMAGE RECONSTRUCTION

From the raw data, a digital image is created. A variety of techniques can be used to accomplish this; these rely on the principles of back projection, iterative formulas, or analytic formulas, either with or without Fourier transformation.⁵ The result is a matrix of numbers; in general, a 512×512 matrix is used in abdominopelvic CT. Each number in this matrix is called a pixel, or picture element. Each pixel corresponds to a volume of tissue or voxel within the patient; the average density of the tissue within the voxel is represented by the pixel value. The difference in attenuation of the contents of a voxel relative to water is defined as the CT attenuation number and expressed in Hounsfield units (HU).⁶

IMAGE DISPLAY

This digital image or number matrix is converted to a visual format for interpretation. A gray scale is used with the densest

Figure 65-1 Three sample positions of data measurement in obtaining a single image.

Data are collected from approximately 1000 positions during each revolution. At each position, measurements are obtained from each detector in the array; although the example shows 16 detectors, in actuality 500 to 1000 are used. The entire group of measurements forms the raw data used to reconstruct the internal structure of the scanned object. (Modified from Sprawls P: *Physical Principles of Medical Imaging*. Gaithersburg, Md, Aspen, 1987.)

materials, such as bone (highest HU), being assigned lighter shades, whereas the least dense, such as air (most negative HU), are assigned darker shades. A problem arises in that display devices are limited to demonstrating approximately 60 shades of gray, and the human eye may distinguish as few as 30 shades; the 4096 CT numbers cannot be simply mapped without conversion. The wide range of numbers is converted for display by window width and level controls. The window level specifies the centering of the gray scale, and the choice of width specifies the numbers over which the gray scale is to extend. For example, if the window level is set to 0 and the width is set to 500, every pixel number below 250 will be black and every pixel greater than 250 will be white; if there are 50 shades of gray, each would be assigned a range of 10 numbers with the middle gray used for the numbers adjacent to 0.

Helical Computed Tomography

Helical or spiral CT involves a continuous rotation of the gantry as the patient is advanced at a steady rate through it, dispensing with the discrete steps of data acquisition in conventional CT.^{4,7} This continuous rotation creates a volume set of raw data that must then be segmented to create planar images. Introduced in 1989, the technology was rapidly accepted and distributed. The major advantages of helical scanning include rapid acquisition, unlimited ability to obtain overlapping images without increased radiation exposure, high-quality multiplanar reconstruction, and absence of respiratory misregistration.⁸

Helical CT introduced several unique new concepts that the physician must understand. The first reflects the relationship between the speed of the table and the speed of the gantry. This is described as the pitch and is defined as the table feed per 360-degree tube revolution divided by the width of the collimated beam (Fig. 65-2). When the patient's movement is equal to the beam collimation, the pitch is 1. Increasing the pitch allows increased coverage in the z direction but with some increase in image noise. Use of pitches greater than 1 also decreases the radiation dose to the patient.⁷

A second important new concept introduced by helical CT is that of reconstruction increment and overlapping

Figure 65-2 Concept of pitch (table increment per revolution of the gantry over collimation). Pitch of 1:1 (top). The table increment is a constant 1 cm/s with a collimation of 1 cm. Pitch of 2:1 (bottom). The table increment is 2 cm/s with the 1-cm collimation. Advantages of pitches greater than 1 include increased coverage (20 cm versus 10 cm in this example with a 10-second acquisition) and decreased radiation exposure. However, there is increased noise and slice profile broadening with increased pitches. In clinical scanning of the abdomen, pitches of 1.3 to 2.0 are frequently used with single-detector helical CT. (Modified from Zeman RK, Fox SH, Silverman PM, et al: *Helical [spiral] CT of the abdomen*. *AJR Am J Roentgenol* 160:719-725, 1993.)

reconstructions. As with conventional CT, once the scan has been obtained, the image thickness cannot be changed. However, because the data acquisition is continuous, the location of the image center along the z-axis may be altered. This has two practical applications: it allows overlapping reconstructions for use in postprocessing without any increase in radiation dose to the patients, and it reduces volume averaging effect, which may lead to improved detection of small lesions⁹ (Fig. 65-3).

The demand to scan faster continued despite the dramatic improvement resulting from helical CT. This demand was met by increasing the rotational speed of the gantry and increasing

Figure 65-3 Use of overlapping images with helical CT. A small lesion may be difficult to visualize because of volume averaging effects if it is centered between two adjacent images (*upper example*), where the “nodule” is centered between the top and bottom images. With the use of a 50% overlap, the nodule would be well visualized on the middle of the three images (*lower example*). There is no additional scanning time or radiation exposure to the patient.

the number of slices obtained with each revolution.¹⁰ Rotation speed has been reduced to a fraction of a second, with most high-end scanners having speeds of less than 0.5 s/rotation. Increasing the number of slices obtained per revolution was the next evolution of CT technology: multidetector helical CT (MDCT), also called multidetector-row CT and multislice CT.¹¹

Multidetector Computed Tomography

MDCT machines segment the detector array along the z-axis of the patient, allowing multiple rows of data in this plane to be obtained simultaneously. Elscint (Haifa, Israel) introduced the first MDCT machine, a dual-slice unit, in 1992. However, it was not until several manufacturers introduced four-channel machines in 1998 that the technology exploded. The technology behind MDCT is fascinating but largely beyond the scope of this chapter. Several reviews and books have been published to which the interested reader is referred.¹²⁻¹⁵ As with other improvements in CT technology, the major advantage of multiple detector rows is an increase in performance that can be used to shorten scan duration, to increase scan range, and to improve resolution. In imaging of the solid abdominal organs, radiologists have exploited both the improved resolution and speed afforded by this new technology.¹⁶ A significant portion of the performance gain has been used to obtain images of the organs multiple times during a single bolus of contrast material.¹⁷

In discussing MDCT, it is important to distinguish between the number of channels and the number of detector rows. For example, manufacturers and radiologists often refer to 4-row or 16-row MDCT; however, this is a misnomer, and referring to 4-channel or 16-channel MDCT is more accurate. The number of data channels determines the number of data streams that can be acquired simultaneously from the detector. The number of detector rows is the number of segmented detectors in the z-axis; this number is often greater than the number of channels¹⁸ (Fig. 65-4). However, as the number of channels increases, this discrepancy decreases.

Figure 65-4 Differentiation of channel from row. Four-channel, 16-row MDCT. In this example, the blue and light purple boxes represent the 16 detector rows. The x-ray beam is collimated to expose the central eight rows. The radiation information obtained from each pair of central detector rows is combined electronically behind the detector to create four data streams, one for each of the four channels. Common usage is to refer to this as four-row MDCT, meaning four-channel MDCT.

Another important new concept must be considered with MDCT: acquisition thickness versus image thickness. Before MDCT, image thickness was an acquisition parameter. Once this was chosen and the patient was scanned, it could not be altered. However, with multidetector machines, image thickness is a reconstruction parameter; that is, one can change the image thickness after the patient has been scanned. Various reconstructed section widths are available; the number of choices varies by the manufacturer. An image cannot be created with an image width thinner than the acquisition collimation. As long as the raw data are available, additional images can be created at a different thickness.

MDCT has been used in imaging of the solid abdominal organs in several ways. There has been a reduction in slice width and scan acquisition time for routine abdomen and pelvis imaging. Scanning of a single organ, such as the liver or the pancreas, at multiple times during the rapid administration of intravenous contrast material (multiphase studies) is much easier to accomplish than on single-detector helical CT and has become part of the routine armamentarium of the radiologist. Finally, the use of very thin images during the arterial phase of injection has become helpful in CT angiography, often combined with routine images of the organ of interest.

Dual-Energy Computed Tomography

Dual-energy CT (DECT) is an emerging technology that promises to add a new dimension to CT imaging. Its utility is based on the principle that the attenuation of each element varies by the energy of the x-ray used to image it. The relationship between x-ray attenuation and x-ray energy is not linear. Rather, because of the photoelectric effect, attenuation spikes when the energy of the x-ray is at or just above the k-shell binding energy of the element. This energy level is known as the k-edge. The k-edge varies from element to element but increases with the atomic number of the element.¹⁹ DECT takes advantage of this phenomenon by imaging the patient at two different tube

Figure 65-5 Increased attenuation of iodine at 80 kVp compared with 140 kVp. Two axial contrast-enhanced images of the abdomen obtained at the same time at 140 kVp (A) and 80 kVp (B). Note the increased attenuation of the aorta and solid organs on the 80-kVp image resulting from the increased attenuation of iodine at 80 kVp. When measured, the attenuation of the aorta increased from 420 to 835 HU. The attenuation of the pancreas increased from 119 to 184 HU.

voltages. This is accomplished either by rapidly switching the tube voltage of a single x-ray tube as it rotates around the patient (rapid switching DECT) or by imaging the patient with a pair of x-ray tubes and detectors oriented at 90 degrees to each other (dual-source DECT). The lower tube voltage is most commonly 80 kVp, and the higher voltage is 140 kVp. Whereas the energy of the x-rays emitted by the x-ray tube is a spectrum of varying energies, the lower the tube voltage, the lower the average energy of the spectrum.²⁰

By determining the attenuation of a voxel at two different tube voltages, DECT has several potential benefits. The first is increased sensitivity to iodinated contrast media. When imaging at 80 kVp, a larger portion of the x-ray spectrum is near the k-edge of iodine (33.2 keV). Therefore, the attenuation of iodine is greater than at higher tube voltages. This increases the sensitivity of the detection of iodinated contrast media (Fig. 65-5).¹⁹ Unfortunately, imaging at 80 kVp generates inherently noisier images than those obtained at a higher tube voltage. This disadvantage is mitigated by blending the noisy 80-kVp image with the “cleaner” 140-kVp image to create an acceptable image quality.²¹ This increased sensitivity to contrast media has been shown to increase the conspicuity of hypervascular lesions in the liver and hypovascular lesions in the pancreas.²⁰

DECT also has the ability to detect certain substances on the basis of their differing attenuation at different x-ray energies. With respect to gastrointestinal imaging, there have been investigations into use of DECT to detect and to quantify hepatic iron and fat stores.²²⁻²⁴ In addition, DECT has been used to detect iodine and to create iodine-only images that aid in lesion detection. Conversely, DECT has also been used to create virtual unenhanced images by removing the iodine from a single-pass contrast-enhanced DECT. These two techniques allow detection of lesion enhancement without the need for a noncontrast CT scan.²¹

Dosimetry and Dose Reduction

There has been a significant increase in both the public and professional awareness of radiation dose in medical imaging.²⁵ As CT is a procedure of relatively high dose and is used for a widening array of applications, it has received a large share of the attention.²⁶ CT scanning is now the highest single

contributor to human-made radiation exposure to the population.²⁶ The National Radiological Protection Board in Great Britain estimated that in 1999, although only 4% of diagnostic procedures were CT scans, they contributed to 40% of overall medical radiation exposure.²⁷ Unfortunately, calculating the radiation dose in CT is complex, leading to difficulty in providing simple answers to questions of dose.²⁸ Important principles include the following: the dose is administered only to a certain volume of the body, not to the entire patient; the dose can vary considerably from scanner to scanner and from image to image, depending on the technical parameters set; and the percentage of the dose delivered centrally compared with the skin dose is much greater with CT than with conventional radiography.^{2,3}

Absorbed dose is the energy absorbed per unit mass; it is measured in the SI unit gray (Gy). Fundamental CT absorbed dose descriptors include volume CT dose index (mGy), which reflects the average radiation dose within a scan volume, and dose-length product (mGy-cm), which reflects the radiation dose over the entire scan length. One or both of these values is displayed on the operator console of newer CT machines.

The other descriptor of importance is the effective dose (mSv), which estimates biologic risk. Effective dose may be calculated by multiplying the dose-length product by a conversion factor that is based on the body part being scanned and the size of the patient. For an adult, the conversion factor for abdominal CT is 0.15.²⁹ The effective dose is almost always the number a clinician or patient wants to know when they ask what the radiation dose of a CT examination is. Typical effective dose values for abdominopelvic CT scans range from 8 to 16 mSv.^{26,30} It is often helpful to remember that the range of background radiation in the United States is 1 to 10 mSv, with an average of about 3.6 mSv. Several excellent reviews are available for those interested in further information.³¹⁻³³

Several strategies exist to reduce radiation exposure due to CT both at the population level and during a given CT examination. Emphasis by the radiologist on performing a CT examination only to provide clinically useful information that will affect the course of treatment is the first step in reducing CT use as a population. Optimizing the study to answer the clinical question the first time avoids radiation from repeated CT studies. Limiting scan length to the area of interest also avoids excess radiation. Finally, consideration of alternative imaging

modalities, such as ultrasound and magnetic resonance (MR), which do not use ionizing radiation, is also important.

In performing a given study, there are several parameters that may be adjusted to reduce the dose to the patient. The key tradeoff involved is between radiation dose and image quality. In general, parameters that reduce radiation exposure to the patient also reduce the number of photons that reach the detector. This reduced sample size increases statistical noise, which is manifested as reduced image quality. Therefore, it is important for the radiologist to understand that although the highest possible image quality is desirable, it often comes at the expense of increased radiation exposure.

Three key parameters that influence both radiation dose and image quality are the tube current-time product, tube voltage, and pitch. The tube current-time product measured in milliamperere-seconds (mAs) is the product of the tube current and the time of rotation. Peak tube voltage (kVp) measured in kilovolts (kV) is the voltage applied to the x-ray tube. Decreases in current-time product result in a linearly proportional decrease in radiation dose. However, this results in an increase in image noise proportional to the inverse of the square root of the decrease in current-time product (e.g., a reduction in half of the current-time product would result in a $1/\sqrt{.5}=1.41$ or a 41% increase in image noise).³⁴ Similarly, a decrease in tube voltage results in reduced radiation dose at the expense of increased noise and other artifacts.³⁴ Finally, pitch is inversely proportional to radiation dose and directly proportional to image noise.³⁴

Although there is no agreed-on value of these parameters that will produce the optimal image, they may be adjusted to yield the lowest radiation dose possible while still achieving diagnostic image quality in a given clinical scenario. One of the most important factors to take into account is the patient's size. Smaller pediatric patients will require a lower tube current-time product, depending on their size.³⁵ Conversely, the obese adult patient will often require an increased tube current-time product and tube voltage for a diagnostic image to be obtained.³⁶

Reconstructed slice thickness is another factor that may influence radiation dose. As discussed before, with MDCT, a given CT data set may be reconstructed at varying slice thicknesses. However, for a given data set, a thinner reconstruction will have more noise than a thicker one. Conversely, given a desired level of image noise, a thinner reconstruction will require a higher dose than a thicker one.³⁷

CT scanner manufacturers have recently implemented a feature known as automated exposure control, which attempts to simplify the process of optimizing dose reduction. With automated exposure control, the operator sets an image quality parameter, the tube voltage, and the desired slice thickness. Then, as the gantry rotates around the patient, the scanner modulates the tube current such that the lowest necessary current is used to obtain the desired image quality. Determining what represents acceptable image quality may be difficult as image quality parameters vary between manufacturers, and individual radiologists interpret image quality differently.³⁴ However, as this technology becomes more commonplace, automated exposure control should become increasingly useful to limit radiation dose in CT.

One additional dose reduction technique on the horizon is iterative reconstruction. Iterative reconstruction is an alternative reconstruction algorithm that requires less radiation exposure than filtered back projection to generate images of similar

quality. The details of this algorithm are beyond the scope of this text. However, the main limitation of iterative reconstruction is that it is a computationally intensive technique that results in long reconstruction times. Although this is an old technique that was used to reconstruct the first CT images, this limitation caused it to fall out of favor. Recent increased interest in reduction of radiation exposure combined with increasing computational processing power has renewed interest in this method. Methods that combine traditional filtered back projection with iterative reconstruction have been found to reduce radiation dose by as much as 25% to 40% while maintaining image quality and acceptable reconstruction times.³⁸ Recent research reports 57% to 88% dose reduction with use of a pure form of iterative reconstruction (model-based iterative reconstruction), albeit with long reconstruction times and some loss of image quality.³⁸ However, with increasing computation power and improving algorithms, iterative reconstruction holds great promise for dose reduction in CT.

Intravenous Contrast Principles

Iodine-based intravenous contrast material is routinely used in CT of the solid abdominal organs. When it is properly used, such contrast material improves lesion detection and characterization. However, when it is used improperly, contrast material can actually decrease lesion detection.³⁹ In the early days of conventional CT, abdominal enhancement was described as consisting of three phases: bolus, nonequilibrium, and equilibrium.^{40,41} Whereas these phases are no longer as critical in protocol planning as they were with conventional CT, scanning of the liver should be completed before the equilibrium phase, which generally begins about 90 to 120 seconds after injection.⁴² This could be relevant when either patient or technical problems cause an unplanned increase in the scan delay.

With helical CT and MDCT, enhancement characteristics of abdominal structures have been more completely studied⁴³ (Fig. 65-6). The *early arterial phase* is a common name given to the period when a significant amount of contrast material is in the

Figure 65-6 Phases of enhancement. The curves display the density of arteries, arterial parenchymal enhancement (such as in hypervascular tumors or the pancreas), and portal venous enhancement of the liver. The boxes demonstrate the timing of acquisition of each phase for a hypothetical scanner. Each of the three phases is acquired while contrast enhancement difference is greatest between the desired structure and other structures.

arterial system but little or no contrast material is in the venous system or organs. In the abdomen, this generally occurs 15 to 25 seconds after the initiation of injection in most patients. The *late arterial phase* describes the time when contrast material is entering hypervascular tumors and vascular organs in significant amounts; this is generally 30 to 45 seconds after the beginning of the injection. Some have termed this the *portal inflow phase*, as contrast material is generally seen in the portal vein also but not in the hepatic veins; however, the enhancement of the liver parenchyma in this phase is primarily due to hepatic arterial flow. Finally, the period from 50 to 80 seconds after the injection is referred to as the *portal venous phase* and is the time during which the liver is maximally enhanced; this delay reflects the predominant portal venous supply of the liver. Contrast material reaches the liver through the portal vein only after it traverses the mesentery and bowel. This phase has also been called the *hepatic parenchymal phase* and the *hepatic venous phase*.⁴³

Iodinated contrast material is available in varying concentrations. Sixty percent iodine concentrations (300 mg/mL) are most commonly used for abdominal applications. However, varying concentrations have been studied, with a recent trend in use of higher concentrations.⁴⁴ One rationale for use of higher concentrations (350 to 370 mg/mL available in the United States, 400 mg/mL elsewhere) is the ability to get a greater number of iodine atoms into the organ of interest with the same injection rate.⁴⁵ Lower injection rates may be safer and easier to use.⁴⁶ Use of higher concentrations has been shown to improve detection of hypervascular hepatocellular carcinoma compared with preparations of 300 mg/mL.⁴⁷

Injection of contrast material should always be performed with a power injector. This ensures that the desired injection rates and timing are achieved. Both the rate at which the contrast material should be administered and the length of the scan delay (time from initiation of the injection of the contrast agent to time of initiation of scanning) have been studied extensively.⁴⁸ As the rapidity of acquisition increased with helical CT and MDCT, a complete reevaluation of contrast agent administration strategies has been required.⁴² Before helical CT, the greatest concern was administration of the contrast agent to maximize the time to equilibrium phase to allow scan completion before equilibrium began. This is now easily accomplished, and the focus has been on determining the strategies to maximize visualization of various normal and pathologic structures at certain points of enhancement.

There are two additional questions to be answered with regard to intravenous administration of contrast material: the amount and method of administration. All currently used iodine-based contrast agents distribute rapidly into the extracellular space. Thus, the enhancement of vessels and organs depends not only on the dose but also on the rate of injection and the length of time from the beginning of the injection to imaging (scan delay) (Fig. 65-7).

The dose of contrast material administered depends on scanner type and the specific organ of interest. Because of the various concentrations available, dose is best considered in grams of iodine. The increased speed of helical CT and MDCT has allowed dose reductions when the primary purpose of contrast is vascular opacification. However, adequate opacification of the hepatic parenchyma to optimize detection of focal lesions probably is not as dependent on speed; it has been recommended that a minimum dose of 38 g (125 mL of a

Figure 65-7 Phases of enhancement with demonstration of timing differences based on machine type. If a series of images through the liver is desired at peak parenchymal enhancement, the scan delay will vary with the length of time the scanner takes to image the entire organ. Shown are two examples: a four-channel MDCT scanner that requires 10 seconds to scan the liver and a single-channel helical scanner that requires 30 seconds to complete the images.

300 mg/mL formulation) should be used with helical scanning.⁴⁹ For general parenchymal organ imaging, a dose of 120 to 150 mL of 300 to 370 mg/mL contrast material is generally used.⁵⁰

The volume of contrast material administered to adults undergoing CT has routinely been held constant regardless of the patient's size. By adjustment of the dose according to the patient's weight, a lower overall amount of contrast material may be used, creating a cost savings while maintaining image quality. A weight-based dose of 1.5 mL/kg was found acceptable in most patients for routine survey examinations.⁵¹

In general, contrast material is injected at relatively high rates to obtain rapid opacification of vessels and organs and to avoid imaging during the equilibrium phase. The degree of enhancement and the time of maximum enhancement are both directly related to the injection rate.⁵² Rates for routine abdominal studies generally are 2 to 3 mL/s; this is adequate to image the abdomen during the portal venous phase of enhancement. With multiphasic imaging, a more rapid bolus helps separate the different phases; for example, with a higher rate, a greater volume of contrast material is administered to obtain a high degree of hepatic arterial enhancement in the liver before portal venous contamination begins.⁵³ Rates for hepatic examinations generally range from 3 to 6 mL/s.

The scan delay is defined as the time between the initiation of injection and the initiation of image acquisition. The delay chosen depends primarily on the phase of enhancement one wishes to image. Routine abdominal studies are ideally performed during the portal venous phase; CT angiographic images are obtained during the early arterial phase and hepatic parenchymal arterial studies during the late arterial phase. The scan delay also depends on how fast the scanner is—one must consider the contrast enhancement at the end of the scan as well as at the beginning. Ideally, the scan is centered at the peak of the desired phase. Thus, with the slowest scanners, one might have to begin before the ideal opacification is reached to ensure that at the end of the scan, the

enhancement phase is still appropriate; conversely, with the fastest scanners, the delay is greater to center the acquisition at the desired enhancement peak (Fig. 65-7). The optimal scan delay depends on the injection rate and volume administered; when the rate is changed, the delay may require adjustment as well.⁵⁴⁻⁵⁷

The terminology used to describe the administration of contrast material in CT varies in the literature, by local custom, and with the organ of interest. Multiphase studies are usually referred to by the number of series obtained after the injection of contrast material; for example, "biphasic" CT of the liver usually includes two contrast-enhanced scans; it may or may not include a precontrast scan. If a precontrast scan were included, some would term this a triphasic examination, whereas others would not.

As the science of contrast agent administration has progressed, patient-dependent factors have become more obvious. Most institutions use nearly the same technique for most adult patients. However, differences in cardiac output, weight, time from last meal, and fluid status affect the actual enhancement obtained on the images.^{58,59} In an effort to tailor the examination to the specific patient, bolus tracking systems are available that initiate scanning when the optimal enhancement has been reached.^{60,61} In general, these systems use a series of low-dose scans obtained at a single location within the abdomen. A region of interest cursor is placed on the aorta or liver, and a threshold density level is set. After the beginning of the contrast agent administration, scans are obtained every second or so until the density measured within the region of interest reaches a threshold value. At that time, the diagnostic scan is begun.

Another technique becoming more popular, particularly with the use of 64-channel CT machines and in CT angiography, is the use of a "saline chaser." This was originally described with a technique of placing both the contrast agent and saline in one injector chamber, but now dual-bore (one piston for the contrast agent and one for the saline) injectors are available as well.⁶² The saline serves two functions: it increases the efficiency of the contrast agent used as no contrast material will remain in the tubing or in the peripheral circulation of the arm at the end of the injection, and it maintains high concentrations of contrast material in the circulation longer by preserving the bolus shape. This in turn has been used to decrease the total dose of contrast material administered.⁶³

Other intravenous contrast agents are being explored, primarily to image the liver with the goal of improving lesion detection and characterization. These contrast agents target either the reticuloendothelial system (Kupffer cells) or hepatocytes. However, iodine is the only intravenous agent currently used routinely in abdominopelvic CT.

Interpretation Principles

The conventional approach to CT interpretation is based on "hard-copy" film. A number of forces have changed interpretation from a film-based environment to a "soft-copy" or monitor-based environment. The number of images obtained in abdominal studies is climbing as multidetector techniques allow the creation of more (usually thinner) images. Multiple phase acquisitions and use of multiplanar reformations have led to the creation of even more images. Filming this number of images is not practical. Picture archiving and communications

system (PACS) methods have helped manage these images as well as allowed enterprise-wide simultaneous visualization of images with central secure data storage.

Certain principles are the same with both film and monitor interpretation. Images should be displayed with window width and level settings appropriate for differentiation of solid-containing, fluid-containing, and air-containing structures (body window: level = 40-70, width = 380-550). Many radiologists find narrower width (liver window: level = 60-80, width = 125-150) images of the upper abdomen helpful, and viewing of these windows is suggested to aid in identification of lesions with minimal density difference from normal liver.^{64,65} Varieties of measurements are made to clarify findings and to include objective data in the radiology report. Regions of interest are created to obtain the average density of the contents inscribed to help lesion characterization. Size measurements on helical data sets are accurate in the axial, longitudinal, or z-axis.⁶⁶ Bidimensional measurements are made by determining the longest single diameter, then the longest dimension that is perpendicular to the first.⁶⁷

Image Postprocessing

One of the most important advantages of helical acquisition is that a true volume data set is obtained. This allows several postprocessing options. The most basic option is planar reformations in the sagittal and coronal planes. These may be helpful in a variety of circumstances. For example, in attempting to delineate the origin of a mass, coronal or sagittal reformations may better demonstrate a fat plane separating the mass from an adjacent organ. In addition, certain structures, such as small vessels or the common bile duct, are often more readily assessed in the sagittal or coronal plane.

Curved planar reformations are another postprocessing option in which a single image is created representing the anatomy along a curved line. This is useful in depicting biliary and pancreatic ductal anatomy and the relationship of tumor to these structures. Curved planar reformation is also useful in depicting stenosis, thrombosis, and aneurysms in vascular structures.⁶⁸ In addition, the ability to depict complex anatomy on a single image is appreciated by referring clinicians.⁶⁸

Maximum intensity projection renderings generate images in which each pixel represents the highest attenuation voxel in a slab of tissue of a set thickness. This slab can be oriented in any plane. Maximum intensity projection reformations are often used with CT angiography to aid in evaluating small vascular structures that are accentuated by this technique. They are also used in surgical planning to help resolve questions of vascular anatomy and the relationship of tumor with adjacent vasculature.⁶⁹

Minimum intensity projection renderings conversely generate images in which each pixel represents the lowest attenuation voxel in a slab of tissue of a set thickness. Minimum intensity projection images are useful in evaluating low-attenuation structures, such as the pancreatic ducts and the biliary tree.⁷⁰

Volume rendering encompasses a wide array of techniques in which a three-dimensional model of the structures of interest is created. With respect to the imaging of the solid organs, it is mainly used with CT angiography to depict vessels. Volume rendering is used in conjunction with maximum intensity projection in addressing questions of vascular anatomy and the relationship of vessels to adjacent tumor.⁶⁹ It is therefore useful

for surgical planning before liver transplantation, liver donation, partial hepatectomy, and partial pancreatectomy.

Volumetry is another postprocessing technique used to calculate the volume of a structure. The structure may be outlined manually or automatically at a workstation over contiguous slices throughout its entire volume. The workstation software then calculates the estimated volume of the structure. Estimation of tumor volume may be useful in assessing response to treatment.⁷¹ Volumetry has also proved useful in presurgical planning before living related liver donation to estimate the volume of the donated liver and the remaining liver after donation.⁷² It is also useful in planning before partial hepatectomy to estimate liver volume after resection.⁷³

These are just some of the more common available postprocessing options. Some, such as multiplanar reformations, may be performed routinely, whereas others are performed only for certain indications. They are often of great utility to the referring clinician as they may depict anatomy and pathology in a manner more easily interpreted by the nonradiologist.

Scanning Protocols

Exact scanning protocols depend on many variables, including the clinical indication, patient-related factors such as weight and venous access, and scanner type and manufacturer. Scanning protocols should be tailored for the specific clinical indication.⁷⁴ Some basic principles are provided here from which exact CT protocols may be derived.

ABDOMINOPELVIC SURVEY

Survey examinations of the abdomen are often obtained for conditions such as abdominal pain, possible abscess, or malignant disease. For general survey examinations, the study is best performed with both oral and intravenous contrast material unless it is contraindicated.⁷⁵ The use of 5-mm-thick images obtained every 5 mm through the abdomen is standard. An injection of 125 mL of intravenous contrast material is used with an injection rate of 3 mL/s. A scan delay of 70 seconds is used for most patients. Approximately 900 mL of oral contrast material is used for most patients, if they can tolerate the enteric intake. However, acquisition section thickness may range from 0.5 to 2.5 mm. The images created for interpretation are usually thicker, from 3 to 5 mm.⁷⁶

As long as the raw data are still in the scanner memory, additional thinner images can be created later if needed. One should be cognizant of the length of time of the injection versus scanning speed. This is usually an issue only in patients with poor intravenous access requiring lower injection rates. For example, if the injection rate is reduced to 1.5 mL/s, the injection will last about 90 seconds. Depending on the acquisition collimation and gantry rotation speed, a scan initiated at 70 seconds could be complete before all the intravenous contrast material has entered the abdominal circulation. To avoid this, one may increase the delay, slow the scanner, or reduce the volume of contrast material. Sample abdominopelvic survey protocols may be found in Table 65-1.

COMPUTED TOMOGRAPHY OF THE LIVER

Specific CT techniques to better evaluate the liver have become routine with helical CT and especially MDCT (Table 65-2).

TABLE 65-1 Abdominal CT Survey Protocols			
	4-Slice	16-Slice	64-Slice
Intravenous contrast agent (300 mg/mL)*	125 mL	125 mL	125 or 100 mL + 50 mL saline chaser
Injection rate	2-3 mL/s	2-3 mL/s	2-4 mL/s
Scan delay	60-70 s	60-70 s	60-70 s
Detector collimation	2.5-5 mm	1-1.5 mm	0.5-0.625 mm
Image thickness	5 mm	5 mm	5 mm

Oral and intravenous contrast agents should be used unless contraindicated.

*Other concentrations of the contrast agent may be used; the volume can be adjusted to keep grams of iodine constant.

Conventional CT cannot be used for specific hepatic imaging protocols. Whereas certain principles of hepatic CT imaging exist, the specific techniques used will vary slightly by the exact indication. Specific protocols may focus on lesion characterization, screening for hepatocellular carcinoma in high-risk individuals, evaluation of cholangiocarcinoma, or preoperative staging and planning. In addition, there are also special techniques involving catheter angiography with CT.

The general principle from which most specific protocols are derived is based on the dual blood supply of the liver.⁷⁷ The normal liver receives approximately 25% of its blood supply from the hepatic artery and 75% from the portal vein. The hepatic arteries will receive contrast material after a peripheral venous injection first, generally beginning at 15 to 25 seconds, depending on injection rate and the patient's circulation time.⁷⁸ Contrast material reaches the portal venous system later as it must first traverse the mesenteric vessels and bowel capillaries. The portal vein begins to enhance about 35 to 40 seconds after the injection of contrast material begins. Finally, at about 60 to 70 seconds, contrast material is identified in the hepatic veins.

In contrast to the hepatic parenchyma, most hepatic tumors are supplied by the hepatic artery exclusively. The appearance of a focal hepatic mass depends on its vascularity and the delay after administration of contrast material.⁷⁹ Hepatic tumors that are hypervascular are generally best seen on late arterial phase images, which are obtained near the end of the phase of exclusive enhancement of the liver by the hepatic arteries, that is to say, when the contrast material just reaches the portal vein, at about 35 to 40 seconds (Fig. 65-8). Images obtained at this time have been referred to in the literature as arterial, late arterial, or portal venous inflow images.⁷⁹ Hepatic tumors that are hypovascular are generally best seen when there is good opacification of the liver by both the hepatic artery and portal vein, but before the onset of equilibrium. This is at 60 to 70 seconds and is identified by contrast material in the hepatic veins. Images obtained at this time may be varyingly referred to as portal venous, parenchymal, or hepatic venous phase images. However, these tumors may not be visualized during earlier phases (Fig. 65-9). This is because the hypovascular tumor receiving a large amount of contrast material may become isodense to the hypervascular liver, which is receiving contrast material from only a portion of its blood supply. The exact timing of each phase in a particular patient may be determined by a test bolus technique.⁷⁷

TABLE 65-2 Hepatic CT Protocols		4-Slice	16-Slice	64-Slice
Precontrast images	Detector collimation	5 mm	1.5 mm	0.5-0.625 mm
	Image thickness	5 mm	5 mm	5 mm
Injection	Contrast volume (300 mg/mL)	125 mL	125 mL	125 mL
	Injection rate	3-4 mL/s	3-4 mL/s	3-4 mL/s
Early arterial phase* (CT angiography)	Scan delay	15 s	15 s	15 s
	Detector collimation	1-1.25 mm	0.75 mm	0.5-0.625 mm
	Image thickness	2 mm	1 mm	1 mm
Late arterial phase (arterial, portal venous inflow)	Scan delay	30 s	30 s	30 s
	Detector collimation	1-2.5 mm	0.75 mm	0.5-0.625 mm
	Image thickness	2-4 mm [†]	2 mm [†]	2 mm [†]
Portal venous phase (hepatic venous, parenchymal)	Scan delay	60-70 s	70 s	70 s
	Detector collimation	5 mm	1.5 mm	0.5-0.625 mm
	Image thickness	5-7 mm	2-5 mm	2-5 mm
Delayed phase [‡]	Scan delay	10-20 min	10-20 min	10-20 min
	Detector collimation	5 mm	0.75 mm	0.5-0.625 mm
	Image thickness	5-7 mm	2-5 mm	2-5 mm

For most indications, three phases are chosen, generally precontrast, late arterial, and portal venous phases. Early arterial images may be performed if desired for surgical planning, and delayed phase images are generally added in evaluation of cholangiocarcinoma.

*With single channel, cannot be combined with arterial phase. Positive enteric contrast material should not be used; neutral or negative enteric contrast material may be administered. A 50% image overlap should be used (reconstruction interval equal to half of image thickness).

[†]Thinner slice images with a softer kernel are created for use in maximum intensity projection and volume rendering angiographic images.

[‡]For use in identification or evaluation of cholangiocarcinoma.

Figure 65-8 Biphasic liver examination of a hypervascular metastasis. **A.** On this late arterial phase image, a 1-cm hypervascular metastasis is identified in the medial segment of the left lobe (*long arrow*). Note that portions of the hepatic artery (*short arrow*) are well seen and contrast material is just entering the portal vein (*asterisk*). **B.** On this portal venous phase image obtained at the same location as in **A**, the lesion cannot be easily identified (*asterisk*).

Figure 65-9 Biphasic liver examination of a hypovascular metastasis. **A.** On this late arterial phase image in a patient with metastatic colon cancer, no hepatic lesion can be identified. **B.** On the portal venous phase image obtained at the same location, the hypovascular metastasis on the lateral segment of the left lobe is easily seen (*arrow*).

The specific acquisition collimation, pitch, gantry rotation, and table speed will vary by scanner type and manufacturer. In general, these parameters are adjusted such that each phase can be accomplished within a 10- to 15-second breath hold. Increasing pitch decreases the radiation dose but increases image noise; in general, pitch should vary from 0.75 to 1.5 for most protocol phases. The reconstruction interval is generally equal to the image thickness, resulting in contiguous images, with the exception of early arterial images to be used for CT angiographic reconstruction, in which the reconstruction interval is generally 50% of the image thickness.

The usefulness of precontrast images has been the subject of some debate. Proponents note the increased sensitivity for certain malignant lesions.⁸⁰ Precontrast images can also be helpful in the identification of focal calcifications. Detractors focus on the relatively small incremental advantages compared with the additional cost and radiation exposure.⁸¹ Acquisition collimation is also generally kept relatively large and image thickness is usually kept at 3 to 5 mm (see Table 65-2).

Early arterial phase images can be separately obtained for three-dimensional reconstructions of the upper abdominal and hepatic arterial trees for use in surgical planning. When these are desired, a high rate of injection (4-6 mL/s) is important. As thin an acquisition collimation and as rapid a gantry speed as possible are used. If three-dimensional reconstructions are anticipated, positive oral contrast material should not be given as it interferes with reconstructions.

Late arterial phase images are used for identification of hypervascular lesions as well as for lesion characterization.⁴³ This requires high injection rates of 4 to 6 mL/s to get adequate amounts of iodine into the liver before portal venous contamination. With higher concentrations of contrast material, slightly slower injection rates introduce the same amount of iodine per unit time. Acquisition thickness ranges from 2.5 mm on 4-channel units to 0.5 mm on 64-channel units. The general principle used is to obtain as thin of a collimation as possible that will allow completion of the scan before a large amount of contrast material has entered the liver through the portal vein. This allows excellent spatial resolution that can be exploited to evaluate the arterial tree during this phase, negating the need for early arterial images. Image thickness of 2.5 to 5 mm may be used. Thinner images may help with identification of small vessels; however, one study demonstrated no improvement in the detection of hypervascular hepatocellular carcinoma with images thinner than 5 mm.⁸²

Portal venous phase images are obtained with parameters similar to those used for routine survey examination of the abdomen. MDCT is begun at 60 to 70 seconds with an acquisition collimation of 0.5 to 5 mm, depending on the number of channels. With MDCT, the image thickness is generally larger than the collimator thickness, usually 3 to 5 mm. Results from several studies comparing different image thickness have had varying results. A study of small lesions (defined as ≤ 10 mm) found that 2.5-mm image thickness was more sensitive than 5-, 7.5-, or 10-mm image thickness.⁸³ However, a later study comparing images of 5-, 3.75-, and 2.5-mm thickness showed no improvement in detection of small metastases with the thinner image thickness, possibly because of increased noise on the thinner images.⁸⁴ Finally, one must consider that 80% of small (10 mm) liver lesions in patients with known malignant neoplasms are benign, and differentiation of small benign lesions from small malignant lesions can be difficult or impossible.⁸⁵ It

is possible that in evaluating for small and very small metastases, an approach different from the routine anatomic one, such as perfusion imaging, will be required.⁸⁶

Delayed scanning can be performed at 10 to 20 minutes after the injection, particularly for the detection or evaluation of cholangiocarcinoma.^{87,88} At this time, contrast material persists in fibrous, dense structures but is decreasing in concentration in most tissues because of renal excretion. Such a delayed acquisition generally would have the same parameters as the portal venous phase sequence.

If bolus tracking or a test bolus is used to optimize timing of the study, the region of interest may be placed over the upper abdominal aorta and a trigger of 100 HU may be used. For the late arterial phase, a delay of 16 seconds from the trigger is recommended. For the portal venous phase, a delay of 50 seconds from the trigger is recommended.⁸⁹ If delayed scanning to assess for cholangiocarcinoma is to be performed, timing of the delayed phase based on the test bolus or bolus tracking is not necessary.

A significant challenge in liver imaging is imaging of sick patients with decreased liver perfusion. This includes patients with cirrhosis, cardiac dysfunction, and portal vein thrombosis. These comorbidities are common in patients undergoing liver imaging. These patients may have decreased enhancement of the liver parenchyma in the portal venous phase that may obscure hypovascular liver lesions. This effect may be partially mitigated by the use of contrast media with higher concentration of iodine or higher volumes of contrast material.⁹⁰

Additional specialized hepatic CT imaging techniques exist but are not routinely used at most institutions. Delayed images at 6 hours after injection demonstrate focal lesions as slightly hypodense as the liver is slightly increased in density because of active excretion of the contrast material by the hepatocytes into the bile.⁹¹ CT angiography and CT portography employ the use of an arterial catheter placed in the hepatic, splenic, or superior mesenteric artery. Images are obtained either during the direct arterial opacification of the liver (CT hepatic angiography) or during the first pass of contrast material through the portal venous system of the liver (CT arterial portography).^{92,93} These techniques have been shown to be most sensitive for focal lesion detection; however, most comparisons predate MDCT.⁹⁴

COMPUTED TOMOGRAPHY OF THE PANCREAS

MDCT scanners have improved pancreatic imaging because of reduced acquisition time, ability to image during multiple phases of enhancement, and excellent multiplanar image reconstructions. MDCT imaging of the pancreas is based on the enhancement pattern of the pancreas in its normal and diseased states. Noncontrast images can be helpful in identifying pancreatic calcifications and calcified common bile duct stones. However, full MDCT evaluation of the pancreas requires the use of intravenous contrast material. Water or negative oral contrast media may be used to distend the stomach and duodenum to make it easier to evaluate for gastric and duodenal wall lesions. Compared with positive oral contrast agents, negative oral contrast agents do not mask possible radiopaque stones in the common bile duct or pancreatic calcifications.⁹⁵ Sample pancreatic CT protocols may be found in Table 65-3.

Contrast-enhanced CT pancreatic imaging is based on multiple parameters, such as iodine concentration, contrast

material volume, and injection rate. The maximum iodine dosage should not exceed 35 to 45 g.⁹⁶ Achieving high-contrast pancreatic enhancement is possible by increasing the injection rate or the concentration of iodine in the intravenous contrast material while keeping the total iodine dose constant. If the injection rate of the contrast material and the total iodine dose are constant, the use of higher concentration contrast media significantly improves pancreatic enhancement compared with lower concentration contrast media.⁹⁷ As a result, high-concentration intravenous contrast media improve pancreatic lesion detection. A weight-based approach to administration of intravenous contrast media may also be used to optimize the iodine dose. An iodine dose of 550 mg/kg can be used for both pancreatic and vascular enhancement, which translates into 1.8 to 2.0 mL/kg, depending on the iodine concentration in the contrast media.⁹⁸

Precontrast CT of the upper abdomen is first performed with 5- to 10-mm slice thickness to cover the pancreas. Subsequent contrast-enhanced imaging of the pancreas has three possible phases: the early arterial phase, the pancreatic phase

(also known as the delayed arterial phase), and the portal venous phase.⁹⁹

The early arterial phase is obtained approximately 20 seconds after the bolus administration of 125 to 150 mL of contrast medium, injected at a rate of 4 to 5 mL/s. This is almost a purely arterial phase with little if any pancreatic enhancement. This phase, although it is not always obtained, allows assessment of the arterial tree in relation to pancreatic disease and may be useful in surgical planning.¹⁰⁰ However, there may not be enough contrast material present within the pancreas for identification of hypervascular or hypovascular lesions.^{100,101}

The pancreatic (delayed arterial) phase is acquired nearly 35 to 40 seconds after administration of the contrast medium. The scan extends from the level of the diaphragm to the inferior aspect of the duodenum with 2-mm slice thickness. During this phase, there is peak enhancement of the pancreas and good opacification of the arterial vascular system.¹⁰² Images obtained in the pancreatic phase can be particularly helpful in identifying both hypervascular and hypovascular pancreatic lesions or vascular involvement by tumor or inflammation¹⁰³ (Fig. 65-10).

TABLE 65-3 Pancreatic CT Protocols

		4-Slice	16-Slice	64-Slice
Precontrast ^{*,†}	Detector collimation	5 mm	1.5 mm	0.5-0.625 mm
	Image thickness	5 mm	5 mm	5 mm
Injection	Contrast volume (300 mg/mL)	125 mL	125 mL	125 mL
	Injection rate	4-6 mL/s	4-6 mL/s	4-6 mL/s
Arterial phase (CT angiography)	Scan delay	15 s	15 s	15 s
	Detector collimation	1-1.25 mm	0.75 mm	0.5-0.625 mm
Parenchymal phase ^{‡,§}	Image thickness	1.25 mm	1 mm	1 mm
	Scan delay	35-45 s	35-45 s	35-45 s
Portal venous phase	Detector collimation	2.5 mm	0.75 mm	0.5-0.625 mm
	Image thickness	2-3 mm	2 mm	2 mm
	Scan delay	60-70 s	70 s	70 s
	Detector collimation	5 mm	0.75 mm	0.5-0.625 mm
	Image thickness	5-7 mm	2-3 mm	2-3 mm

Up to four phases may be obtained through the pancreas; however, most institutions perform only three (choosing either the arterial phase or parenchymal phase) to limit radiation dose. Enteric contrast agents should be neutral or negative.

^{*}Most useful in evaluating patients with chronic pancreatitis or biliary obstruction; not generally used for routine mass evaluation.

[†]This may be restricted in the z-axis to cover only the pancreas.

[‡]In many circumstances, this can also be used for vascular assessment and reconstructions (CT angiography) with minimal venous contamination.

The raw data can be reconstructed into an additional data set with image thickness equal to detector collimation and with 50% overlap.

[§]In cases of known or suspected hypervascular pancreatic tumor (i.e., neuroendocrine), this phase can be expanded to include the liver for assessment for metastasis.

^{||}Generally includes the entire abdomen.

Figure 65-10 Patient with symptoms and laboratory abnormalities consistent with an insulinoma. **A.** Image obtained during the pancreatic phase clearly demonstrates the hypervascular tumor (arrow) in the pancreatic head adjacent to the superior mesenteric vein. **B.** The tumor is almost impossible to identify on the portal venous phase image obtained at the same level. *, superior mesenteric vein.

The portal venous phase is acquired at 70 to 80 seconds after the administration of the contrast medium. For the portal venous phase, an acquisition is performed covering the entire upper abdomen with 2.5- to 5-mm slice collimation. Portal venous phase images improve visualization of the hepatic parenchyma, hypovascular hepatic metastases, and involvement of venous structures by tumor.⁹⁹

If a bolus tracking or test bolus technique is used, the region of interest is placed over the aorta just above the pancreas and a threshold of 50 to 100 HU is used to trigger the study. With this technique, scanning for the arterial phase begins 8 seconds after the trigger, the pancreatic phase starts 25 seconds after the trigger, and the portal venous phase begins 50 seconds after the trigger.⁸⁹

Future Directions

The history of CT has been one of continuous improvement, usually measured in resolution and speed. Several significant leaps forward have occurred, most notably the introduction of helical and multidetector technologies. Although one major goal, the isotropic voxel, has been achieved with 64-channel machines, the demand for continued improvement persists.

Whereas machines with even greater numbers of channels have been developed, the pursuit of speed and anatomic detail is only one avenue of future development and one that has led to its own set of questions. How can the new larger data sets generated by these machines be interpreted efficiently? With the potential for thousands of images to be generated for a single examination, what are the optimal reformations of the CT data set that will maximize efficiency of interpretation without sacrificing the diagnostic accuracy of the examination? Finally, what are we to make of those small findings of questionable clinical significance that are now being revealed with the improved anatomic detail offered by modern CT (e.g., the small pancreatic cystic lesion)?

Another area of future development is in the techniques that provide the radiologist with information beyond anatomy and attenuation. DECT is in its early stages, and although a few applications of abdominal imaging have been conceived, this is an area of active investigation that has the potential to provide the radiologist with increased contrast sensitivity as well as potentially clinically relevant information about the chemical composition of the tissue being imaged. Another area of active interest is the development of perfusion CT in the abdomen and pelvis, particularly of the liver.¹⁰⁴⁻¹⁰⁶ Following the pathway of many CT innovations, this technique is becoming increasingly important in neuroradiology, and applications in the body (where cardiac and respiratory motion as well as greater z-axis coverage presents additional challenges) may not be far behind. Perfusion is an area of great research interest that may have practical clinical benefits as well. Comparison with MR perfusion techniques will have to be made, particularly in light of the potentially high radiation dose of perfusion CT.

Finally, the central issue facing CT is that of radiation. As the number of CT examinations performed annually continues to increase and the radiation dose from these examinations increases as well, CT faces increasing scrutiny from public health officials, the media, and the general public. In the near future, CT will surely remain the predominant cross-sectional imaging modality, but in the long run, concerns about the effects of radiation as well as the increasing availability of MR and improvements in ultrasound have the potential to decrease the dominance of CT in the imaging armamentarium. As might be expected, manufacturers have stepped up to the plate, offering techniques such as automated exposure control and iterative reconstruction as described earlier. Improvements in these techniques as well as the development of new hardware- and software-based techniques to decrease radiation dose will be crucial to maintaining the long-term relevance of CT.

CHAPTER OUTLINE

Basic Physics

Recent Developments

Doppler Ultrasound

Ultrasound Contrast Media

Ultrasound Artifacts

Liver

Gallbladder and Biliary Tract

Pancreas

Spleen

Ultrasound is an ideal modality for examination of the solid abdominal viscera. It is relatively inexpensive and portable and does not require the use of potentially harmful ionizing radiation or contrast agents. It enables real-time examination and can be used in the emergency department and by the bedside in the wards. Continual improvements in ultrasound technology and computing during the six decades since medical ultrasound was first developed have ensured that it remains the first-choice modality for many applications within the abdomen. Ultrasound has several advantages over computed tomography (CT) and magnetic resonance imaging (MRI), including cost (and hence ease of access), real-time imaging, portability, lack of ionizing radiation, and absence of contraindications, although the cross-sectional modalities are often complementary. Further advances in ultrasound technology will ensure that it retains a central role in abdominal imaging for the foreseeable future.

The first use of medical ultrasound was documented in Austria in 1942 by Karl Dussik, who imaged the ventricles of the brain and brain tumors. Another pioneer of medical ultrasound, Ian Donald in Glasgow, built on innovations in the fields of sonar, radar, and ultrasonic flaw detection in metals to image uterine fibroids and ovarian cysts. He also published a paper entitled "The Investigation of Abdominal Masses by Pulsed Ultrasound" in 1958.¹ Several technologic innovations were necessary to drive ultrasound forward as the commonplace medical imaging technique we know today. The first static arm commercial medical scanners were marketed in the 1960s, but the technique was slow and the machines were cumbersome. Real-time scanners soon replaced static arm scanners. These early scanners used the A-mode technique, in which the amplitude of returning echoes along a single line was displayed on an oscilloscope screen. Later B-mode compound scan images were composed of only black and white. Gray-scale imaging improved

interpretation and is now the standard for abdominal imaging. The development of the transistor and later the integrated circuit improved signal generation and amplification. All modern machines now employ digital signal processing techniques, and improvements in the design and manufacture of probes have allowed the development of compact, robust, and versatile probes for a variety of applications.

The real-time nature of imaging with ultrasound lends itself particularly well to problem solving. Movement with respiration can be examined, tubular structures can be followed, and structures can be examined in different planes. Ultrasound can aid interventional procedures, such as fine-needle aspiration, core biopsy, and drain placement, and it is the modality of choice for guiding interventional procedures within the abdominal solid organs,² although on occasion it may be necessary to supplement it with fluoroscopy, CT, or MRI. However, the real-time nature of ultrasound requires competence on the part of the ultrasonographer or sonologist performing the examination. Although the examination is performed in real time with up to 60 frames per second, only a fraction of these are saved as representative images for future review. Thus the experience of the operators is important because they will decide on the images to store. Picture archiving and storage (PACS) systems have enabled more still images to be stored without incurring the cost of printing film and may also allow the storage of cine loops to show dynamic processes.

Ultrasound enables blood flow to be easily demonstrated without the need for nephrotoxic contrast agents, and neither the patient nor the operator is exposed to harmful ionizing radiation. The ability of ultrasound to differentiate between solid and cystic structures is a particular strength.

Basic Physics

Medical ultrasound uses short pulses of sound waves that are transmitted and received by the transducer (Fig. 66-1). A coupling gel is used to facilitate the transmission of sound waves to and from the probe. This matches the acoustic impedance of the probe to that of tissue and eliminates air gaps between the probe and the skin. The basic element of most current transducers is a piezoelectric crystal that emits a sound wave when a voltage is applied to it (transmission) and generates a voltage when the reflected sound wave returns to it (reception). The voltages produced by each crystal on receiving reflected sound waves are converted into digital signals by an analog to digital signal converter and processed by the ultrasound machine to form the image. Future transducer designs may use alternative methods of transducer construction,³ but the principles of sound wave generation and reception will remain the same. The probe contains multiple crystals arranged in a strip or a grid. There are typically 128 individual crystals within a transducer

Figure 66-1 Components of an ultrasound transducer. The crystal element has piezoelectric properties. (From Curry TS, Dowdey JE, Murry RC: *Christensen's Physics of Diagnostic Radiology*, 2nd ed. Philadelphia, Lea & Febiger, 1990, p 328.)

Figure 66-2 Hepatic cirrhosis. Superficial aspect of the liver scanned with a 7-MHz linear transducer showing nodular surface due to cirrhosis.

array, and they can be independently activated; this allows the ultrasound beam to be electronically steered and focused. Earlier designs used mechanical devices to steer and focus the beam, but these have largely been superseded by electronic controls. The best resolution of an image is within the focal zone, and focusing allows the focal zone to be varied according to the area of interest being examined. The beams of array transducers can be focused on both transmit and receive. Some transducers allow multiple focal zones to be selected to increase the effective focal zone, but this will reduce the frame rate or temporal resolution of the scan.

Several factors have to be taken into account in considering the most appropriate choice of transducer for a given application. Modern transducers suitable for abdominal imaging include linear arrays, curved linear arrays, and sector scanners. Linear arrays (typically 7–12 MHz) provide excellent resolution at the expense of penetration and field of view. They are ideal for superficial lesions or for examining the surface of abdominal viscera, such as the liver (Fig. 66-2). The field of view can be extended by the use of trapezoidal imaging (Fig. 66-3) or compound (or extended field of view) imaging, in which the probe is moved across a structure and the ultrasound machine “stitches together” the images to produce a panoramic image. This is useful for large superficial lesions, such as soft tissue tumors (Fig. 66-4). Curved linear (or curvilinear) arrays are less effective for the examination of superficial structures but provide better penetration (because of their lower frequencies) and a wider field of view. Sector scanners have a limited role in routine abdominal ultrasound but do provide a wide field of view with a small footprint, which can be useful when access is limited, for example, in examining the pediatric abdomen. A compromise must be reached between penetration and resolution, which are inversely proportional. Raising the frequency of the transmitted ultrasound pulse will improve resolution because

Figure 66-3 Trapezoid scan. A trapezoid scan area can be selected with some linear transducers to extend the field of view but maintain the resolution of a high-frequency linear transducer.

of shortening of the wavelength, but it will also decrease the penetration as high frequencies are attenuated more than low frequencies are (attenuation of the sound wave is proportional to frequency). Many modern transducers allow the operator to vary the transmitted frequency within a certain range without having to change probes, for example, from 1 to 5 MHz for a typical curvilinear probe. Most modern ultrasound machines will select the transmitted frequency on the basis of the user's selection of presets, optimizing the image for detail or resolution (high frequency) or penetration (low frequency).

Figure 66-4 Extended field of view demonstration of abdominal wall desmoid tumor.

Figure 66-5 Specular versus nonspecular echoes. Specular reflectors are large interfaces that must be close to the perpendicular of the beam path for the reflected wave in many directions. Some of the wave returns to the transducer. (From Sarti DA: *Diagnostic Ultrasound: Text and Cases*, 2nd ed. Chicago, Year Book Medical, 1987, p 10.)

Sound waves interact with the tissues of the body in three main ways: reflection, absorption, and scatter. The terminology used to describe ultrasound findings is a description of the brightness of the structure; the more sound energy reflected back to the transducer, the brighter the object on the image. Objects are described as hypoechoic (darker than adjacent structures), isoechoic (the same brightness as adjacent structures), or hyperechoic (brighter than adjacent structures). Anechoic structures appear black and indicate fluid. Internal echoes may be caused by debris, septations, or artifacts. Often the liver is chosen as a reference in the abdomen, but care must be taken to ensure that the reference organ is of normal reflectivity and not abnormal due to fatty infiltration, for example. The amount of energy reflected back to the transducer depends on several factors. The simplest form of reflection occurs when sound waves encounter a flat interface perpendicular to the beam with a large disparity in the velocity of sound between the adjacent tissues; this is termed a specular reflector and will appear as a well-defined bright line (Fig. 66-5). Smaller interfaces (0.1-1 mm in diameter) may cause scattering in all directions. Only a small fraction of the transmitted energy is returned to the probe, but when multiple such structures are present, the interference pattern between echoes produces a visible texture.

Figure 66-6 Sound wave transmission and reflection. The percentages of sound transmission and reflection at different interfaces (A-D) are illustrated. This is for the amplitude of a wave. (From Sarti DA: *Diagnostic Ultrasound: Text and Cases*, 2nd ed. Chicago, Year Book Medical, 1987, p 8.)

This process is responsible for the ultrasound appearance of liver, spleen, and kidney parenchyma.

Sound waves propagate through tissues at different velocities, and when there is an interface between different tissues, the sound may be reflected or refracted (just as light may be reflected or refracted by a prism of glass). The greater the difference in velocity between the adjacent tissues, the greater proportion is reflected (if the incident angle of the beam is large) or the more the beam is refracted (if the incident angle of the beam is smaller) (Fig. 66-6).

Recent Developments

Ultrasound machines continue to rapidly evolve with the introduction of new technology. Although the principles of physics remain the same, manufacturers have developed new methods of probe construction, ultrasound generation, and postprocessing algorithms. Often these are assigned brand-specific trademarked titles that may be rather opaque to the user.

Many ultrasound machines now allow the user to select a real-time compound imaging mode, whereby the area to be examined is insonated from several different directions by electronic beam steering for transmission and reception. The

displayed image is an average of the images derived from different insonation angles. This has been shown to improve overall image quality, to increase lesion conspicuity, and to reduce artifact.⁴ However, it does reduce the frame rate and can lead to image blurring if the transducer or the subject is moving.

A recent development that is now standard on most machines is tissue harmonic imaging. “Conventional” imaging without harmonics is known as fundamental imaging because only the fundamental transmitted frequency is used for transmission and reception. Tissue harmonic imaging was originally proposed for use with an ultrasound contrast agent, but it has been shown to improve visualization of abdominal structures without the use of contrast agents.^{5,6} The shape of the transmitted waveform changes as a sound wave is propagated through tissue, particularly in the focal zone, where the intensity is high. Tissues resist compression more than expansion. This is termed nonlinear behavior. The waveform of the reflected pulse is altered and contains higher frequencies than the transmitted pulse. The higher frequencies are multiples of the transmitted fundamental frequency, called harmonic frequencies. At present, it is usually the second harmonic (twice the fundamental frequency) that is used for imaging, but higher multiples may also be used. The fundamental frequencies are electronically filtered out after reception, leaving only the harmonic frequencies. The harmonic frequencies travel through the tissues only once on the return to the probe and therefore are attenuated half as much as an identical frequency transmitted and received by the probe. There is less scatter, particularly in obese patients, in whom subcutaneous fat and superficial muscle layers cause scatter and attenuation of the fundamental frequencies, which may cause a haze of echoes, degrading the image on fundamental imaging. Artifacts such as side and grating lobe artifacts that degrade fundamental images are also reduced because the weak side and grating lobes are not powerful enough to produce harmonic frequencies. The images are clearer, and tissue harmonic imaging may improve diagnostic ability in challenging patients.⁷ Phase inversion imaging also exploits the nonlinear behavior of tissues but employs a different technique from frequency-based tissue harmonic imaging.^{8,9} Two pulses are sent with 180-degree phase difference. If the pulse is reflected in a linear fashion, the reflected waves will cancel each other out. If the waves are reflected in a nonlinear fashion, the waves will not cancel out and are used to form the image. Phase inversion harmonic imaging reduces the frame rate because of the need to transmit twice as many pulses, but the spatial resolution is better than that of frequency-based tissue harmonic imaging.

Three-dimensional and four-dimensional ultrasound applications are established in obstetric ultrasound,¹⁰ but their value is yet to be proved in abdominal imaging.¹¹ Improvements in processing and probe technology have made real-time three-dimensional volume rendered and multiplanar reconstruction imaging possible. An acquisition of a volume of data in a fashion akin to helical CT allows retrospective reconstruction of multiplanar reconstruction views and surface rendered images.

Doppler Ultrasound

The examination of blood flow with Doppler techniques is a valuable addition to real-time gray-scale abdominal ultrasound. The wavelengths of a transmitted sound pulse and the received pulse differ when sound waves are reflected from a moving surface. The wavelength shortens when the reflector is moving

Figure 66-7 Color Doppler ultrasound scan showing normal flow in the left and right branches of the portal vein. Red represents flow toward the transducer, and blue, flow away from the transducer.

toward the transducer and lengthens when it is moving away. The change in wavelength is accompanied by a change in frequency and phase and is termed the Doppler effect. The Doppler frequency (or phase) shift is measured, and the velocity and direction of blood flow can be calculated. One method of displaying the information is as color flow, in which a color map of flow is superimposed on a gray-scale real-time image. Convention dictates that blood flow toward the transducer is red and blood flow away from the transducer is blue, although the operator may invert this. Color flow Doppler is used in the abdomen to examine the arterial tree, the portal venous system, and the systemic veins (Fig. 66-7). It may also be used to examine vascularity within the solid organs, for example, within or surrounding a mass lesion. The box displaying the color information can be resized and moved to include different parts of the image. A compromise between the color box size and the refresh rate of the image must be reached as an increased color box size will slow down the refresh rate of the image.

Power Doppler is a similar technique, but the total power of the reflected Doppler signal is displayed. There are no velocity data and therefore no indication of the direction of flow, but there are some advantages of power Doppler over color flow Doppler in certain situations.¹² Power Doppler is more sensitive to slow flow and, unlike color Doppler, can display flow that is almost perpendicular to the beam. Background noise appears as brightly colored speckles in color Doppler that can be distracting, whereas in power Doppler the background noise is dark, allowing higher gains to be used. It is thus a useful technique when the demonstration of low flow is needed but the direction of flow is not important.

The waveform and the direction of flow in vessels may change in disease states, such as portal hypertension. Pulsed-wave Doppler displays the flow velocity as a waveform, and this is often combined with gray-scale imaging as duplex imaging (Fig. 66-8). The flow is measured in a small sample volume that can be placed on the region of interest. The operator can adjust the position and the size of the sample volume. If quantitative measurement of flow is required, a correction has to be made as the Doppler beam is at an angle to the blood flow. The angle

Figure 66-8 Color and pulsed-wave Doppler examination of the liver illustrating normal flow in the middle hepatic vein.

between the blood flow and the interrogating Doppler beam should be kept as small as possible; it is not possible to obtain a reliable Doppler velocity measurement if this angle exceeds 60 degrees.¹³ This quantitative data can be used to assess vascular resistance, for example, within a transplanted liver.

Ultrasound Contrast Media

Conventional ultrasound does have some limitations in the detection and characterization of liver lesions. Alternative cross-sectional imaging techniques, such as CT and MRI, have often been used to complement ultrasound to overcome these limitations. Ultrasound contrast agents have been developed to increase the sensitivity of ultrasound to small liver lesions and to improve the characterization when lesions are detected on the basis of their perfusion properties. The first-generation ultrasound contrast agents were based on air-filled bubbles and required high acoustic pressures (high mechanical index) to break the bubbles. Contrast enhancement was short-lived. Second-generation contrast agents are now available. These form small bubbles filled with gases other than air, such as sulfur hexafluoride,¹⁴ and allow real-time scanning at a low mechanical index depicting the different phases of blood flow, which is particularly useful in the liver. The appearances of a lesion in arterial, portal venous, and sinusoidal phases (15-35, 35-90, and 90-240 seconds, respectively) can be observed.¹⁵

Most modern ultrasound machines include technology that will allow imaging with contrast agents, but an estimated 60% of ultrasound machines currently in use worldwide do not have the capability.¹⁶ The contrast agent is administered through an intravenous cannula as a rapid bolus followed by a saline flush. The area is then scanned continuously to depict the different vascular phases, and the images are often recorded as a cine clip to allow later playback. Repeated injections of contrast agent are possible, if necessary, as the agents are of low toxicity.¹⁷

The detection of subcentimeter liver metastases is improved when contrast media are used.¹⁸ Contrast media can also be useful in differentiating benign from malignant tumors and characterizing the lesions.^{19,20} It has been suggested that a contrast agent should also be used in the assessment of abdominal trauma,²¹ in which it may be added to the FAST (focused assessment with sonography in trauma) protocol.²²

The use of ultrasound contrast agents remains highly variable, despite some encouraging clinical results. This is due to

many factors, including workflow issues, availability of suitable ultrasound machines, and remuneration. It seems unlikely that they will become a method of choice for characterization of liver lesions, as some proponents suggest.²³

Ultrasound Artifacts

The sonologist should be familiar with common artifacts to minimize their effect on image quality and to avoid confusion with significant pathologic changes,²⁴ although some of the processes described as artifacts can be helpful in interpreting images.

Several assumptions are made in forming an ultrasound image. It is assumed that the ultrasound beam travels in a straight line from the probe and in the body. The velocity of the sound wave is assumed to be constant on the path, and the received echoes are assumed to have traveled in a straight line back to the probe. If any of these assumptions are incorrect, an artifact will be produced.

If the ultrasound wave is propagated through a substance with reduced attenuation compared with the surrounding tissues, the region beyond it will appear brighter or more echogenic. This is due to the fact that a time gain compensation function is applied to the image, whereby the received echoes are amplified proportional to the time interval between pulse transmission and echo reception. The sound wave is attenuated as it passes through a structure, and the reflected echoes are also attenuated on their return to the transducer. If time gain compensation were not applied, deeper structures would appear unacceptably dark. If a structure, for example, a fluid-filled cyst, transmits sound waves effectively with little attenuation, the tissue beyond the cyst will appear brighter than equivalent adjacent tissue (Fig. 66-9). This phenomenon is called acoustic enhancement, and it is an important feature of fluid-filled lesions. Conversely, if a structure attenuates more than the surrounding tissue, tissues beyond it will appear darker and lie within the acoustic shadow. This is typical of solid lesions (Fig. 66-10). A very reflective surface, such as bone or air, will reflect the ultrasound beam and appear as a bright line with a very dark shadow beyond (Fig. 66-11). The ability to differentiate between solid and cystic lesions is an important strength of ultrasound. Gas collections and gas within the bowel tend to produce "dirty" shadows, which are less clear than the shadows produced by a solid lesion such as a calculus.²⁵

Figure 66-9 Simple hepatic cyst. Note the lack of perceptible wall, the anechoic contents, and the posterior acoustic enhancement.

Figure 66-10 Multiple solid hepatic lesions from metastatic neuroendocrine tumor. Note the hypoechoic rims, echoes within the lesions, and lack of posterior enhancement, differentiating them from cystic structures.

Figure 66-11 Single large gallstone. Note the bright anterior surface due to strong reflection and the posterior acoustic shadow.

Reverberation artifacts are a common source of image degradation that may mask disease. They occur when sound waves bounce back and forth between a strong interface and the transducer. As the reflections increase the length of the path, the artifact is seen deep to the interface. Such artifacts are commonly seen in the superficial aspect of the urinary bladder or in the near field of the liver.

Large specular reflectors, such as the air-pleura interface at the diaphragm, can produce artifactual structures to appear beyond them. As an example, the sound wave passes through the structure, such as a lesion in the liver, on the transmission path. Part of the sound wave is reflected back to the transducer and produces the appearance of the lesion in the correct location, but some passes through the lesion and is then reflected back toward the transducer by the right pleural-aerated lung interface acting as reflector. These sound waves will arrive at the transducer later than the “true” echoes from the liver lesion, and thus the artifactual structure will be placed deeper in the body on the display, beyond the reflecting surface. Common examples include liver lesions reflected posterior to the right hemidiaphragm (Fig. 66-12) and apparent pelvic masses reflected posterior to gas-containing loops of bowel in the pelvis.

If there are two or more reflectors close to each other, the sound waves may bounce back and forth between them and produce a comet-tail or ring-down artifact. Ring-down is an ultrasound artifact that appears as a solid streak or a series of parallel bands radiating away from the causative structure, which appears as bands of bright lines posterior to the reflector, the lines becoming shorter and less intense the deeper they are. Examples of causative structures include Rokitsky-Aschoff sinuses within the gallbladder wall (Fig. 66-13), gas in the biliary tree (Fig. 66-14), and surgical clips. Color Doppler will show a twinkle artifact analogous to a comet tail.

Refraction occurs when there is an oblique interface between tissues with different acoustic velocities. This is most commonly seen when the beam passes through the rectus muscles and can

Figure 66-12 Mirror image artifact. Hemangioma (arrow) within the right lobe of the liver reflected in the right pleura-lung interface (the bright line curving superior to the liver) to produce an apparent, artifactual lesion in the right lung base.

Figure 66-13 Comet-tail or ring-down artifact. Comet-tail artifact (arrow) arising from strongly reflective small cholesterol crystals in Rokitansky-Aschoff sinuses in the anterior gallbladder wall.

produce duplication of deeper structures. Movement of the probe eliminates the artifact.

Liver

Ultrasound of the liver is one of the most common examinations in a general ultrasound practice. Information can be gained about the liver echotexture in diffuse liver disease, and focal liver lesions can be characterized as cystic or solid. It may be used as an alternative or an adjunct to CT, and ultrasound is frequently used to guide needle biopsy and drainage procedures.

It is important to ensure that all segments of the liver are examined. Representative images are captured and recorded on film or a PACS system, but these serve only to demonstrate key anatomic structures or selected views of pathologic findings.

The operator makes use of the dynamic nature of real-time ultrasound to differentiate between normal and abnormal. The person reporting static images must therefore be satisfied that the operator has covered the entire liver and has sufficient experience to recognize pathologic changes. A cross section of a fluid-filled structure, such as a hepatic vein, may have similar appearance to a cystic lesion on a static image; but in real time, it can be followed by sweeping the transducer from side to side or turning the transducer through 90 degrees, and the tubular nature is appreciated in longitudinal section. A sweeping motion may also make subtle areas of altered echogenicity more apparent.

Appreciation of the anatomy of the liver is important for ensuring adequate coverage of the liver and for localizing lesions. The porta hepatis is the point at which the portal vein and hepatic artery enter the liver and the common hepatic duct leaves the liver. The plane of the porta hepatis lies approximately transversely. The portal vein divides into left and right branches before entering the liver itself; the anatomy of the hepatic artery is subject to much variation but always lies anterior to the portal vein. The artery lies medial to the common hepatic duct; in 90% it passes posterior to the duct, but in 10% it passes anteriorly. The right portal vein passes laterally in the liver before dividing into anterior and posterior branches; the left passes anteriorly and superiorly in a C shape.

The vascular structures of the liver are important in dividing the liver into the hepatic segments as defined by Couinaud,^{26,27} which enables accurate localization and assessment of the resectability of lesions, although the system is based on the fetal rather than on the adult pattern of circulation. Segment I is the caudate lobe, which receives blood from both the right and left portal veins; it also drains into the inferior vena cava (IVC) through its own short veins (often not visible on ultrasound). It is often spared in early diffuse liver disease, such as cirrhosis, or in hepatic vein occlusion (Budd-Chiari syndrome). Segments II and III are supplied by the left portal vein and divided by the plane of the left hepatic vein. Segment IV corresponds to the quadrate lobe and is separated from segments II and III by the umbilical fissure. A plane between the IVC posteriorly and the gallbladder fossa anteriorly divides the left and right lobes of the liver and corresponds to the line of the middle hepatic vein. The plane of the right branch of the portal vein may be used to divide segment IV into IVa superiorly and IVb inferiorly. The right lobe of the liver consists of segments V to VIII. The plane of the anterior and posterior branches of the right portal vein divides the right lobe into superior (VIII anterior and VII posterior) and inferior (V anterior and VI posterior) segments. The right hepatic vein divides the anterior from the posterior segment. The use of segments to describe liver anatomy has become more important with increasing correlation between different cross-sectional modalities and the use of interventions such as segmental resection and radiofrequency ablation of focal hepatic lesions (Fig. 66-15).

As the liver is a large organ, a systematic approach to its assessment with ultrasound is required to show representative images of the liver segments. The patient is initially positioned supine, although it may be necessary to rotate the patient onto the left side or into the left posterior oblique position during the examination. The patient is asked to take a deep breath in and to hold it as inspiration will move the liver and spleen caudally, making them more amenable to examination from the subcostal position. If it is not possible to image the entire liver

Figure 66-15 Segments of the liver as described by Couinaud. (From Meire H, Cosgrove D, Dewbury K, Farrant P: *Clinical Ultrasound: A Comprehensive Text—Abdominal and General Ultrasound*, vol 1, 2nd ed. London, Churchill Livingstone, 2001, p 167.)

from a subcostal transducer position, an intercostal approach may be necessary. This is best achieved with the patient in a left posterior oblique or left lateral decubitus (left side down) position. The liver should be thoroughly assessed in both transverse and longitudinal planes with a curvilinear transducer (5-1 MHz). Before any images are taken, the liver is quickly surveyed in both the longitudinal and transverse planes with a maximum sector width. This gives the operator an opportunity to view the liver parenchymal characteristics and to adjust the system settings accordingly to optimize the image, to check for any masses or cysts and abnormal liver contour and abnormal areas of echogenicity to determine whether the scan will be intercostal or subcostal, and to determine if there is hepatomegaly or a Riedel lobe and therefore take additional images to document this.

The transducer is obliquely positioned and angled subcostally toward the patient's right shoulder. With a continuous sweeping motion, the transducer is moved from the most lateral portion of the right lobe of liver through to the porta hepatis. When the most lateral portion of the left lobe of liver has been visualized, the transducer is rotated 90 degrees clockwise into a transverse position. The transducer is then angled in a cranial direction from a subcostal position to visualize beyond the superior portion of the left liver lobe. From this position, the transducer is moved caudally through the superior portion to the inferior aspect of the left liver lobe. This transverse scan is repeated on suspended inspiration throughout the whole liver, finishing at the inferior aspect of the right liver lobe. As soon as this general liver survey is over, the transducer is returned to the initial oblique position and angled subcostally toward the patient's right shoulder.

With the transducer in a sagittal orientation, the patient inhales and the depth of the image is adjusted so that the most lateral aspect of the right liver lobe dome and the diaphragm are shown. Adjusting the gain and time gain compensation to optimize the image will ensure an even distribution of echoes from the near field to the far field, thus giving the liver its normal homogeneous echotexture. If the liver is of a heterogeneous echotexture, this must be shown with careful adjustment of the gain and time gain compensation. The liver echogenicity

Figure 66-16 A linear transducer (7-12 MHz) probe was used to examine this cholangiocarcinoma metastasis (*) close to the surface of the liver. Linear transducers have better near-field resolution but are limited in their penetration. They are therefore suited to superficial lesions.

should be compared with that of the right kidney and an image recorded including both in one view. The liver parenchyma is normally less echogenic than the kidney. If the liver is more echogenic than the kidney, it may be due to fatty infiltration of the liver parenchyma. The transducer is moved more medially until the IVC is visualized with the caudate lobe anterior and posterior to it. The portal triad (portal vein, hepatic artery, and common bile duct) is demonstrated at the porta hepatis. Medial to this is the gallbladder fossa, the ligamentum venosum, and a complete view of the caudate lobe. The left lobe including the left hepatic vein is then imaged.

From the longitudinal position, the transducer is rotated 90 degrees clockwise into a transverse position. The left lobe of the liver is imaged to show the left hepatic vein and the left portal vein. The next image is of the left, main, and right hepatic veins draining into the IVC. These are imaged in gray scale and with color Doppler to show nonobstructed venous flow. The next image should document the ligamentum venosum and caudate lobe. Overall gain and time gain compensation adjustment may be required to adequately visualize the caudate lobe as it may appear hypoechoic compared with the rest of the liver because of attenuation of the ultrasound beam by the left portal vein or the liver fissures. The hockey stick-shaped bifurcation of the main portal vein (MPV) into the left and right branches should then be imaged. The right lobe, including the right branch of the portal vein and the right hepatic vein, is examined.

A higher frequency linear probe (8-4 MHz) may be used to examine the surface of the liver for nodularity or superficial lesions (Fig. 66-16). Fine surface nodularity in cirrhosis appears as a broken line on the surface of the liver.²⁸

Any masses, cystic lesions, or abnormal liver areas that are discovered during the scan are imaged separately in both the

Figure 66-17 Nonocclusive thrombus in the right portal vein. Nonocclusive thrombus in the right portal vein (calipers in **A**) seen on gray-scale (**A**) and color Doppler (**B**) images.

longitudinal and transverse planes and characterized. They should be labeled according to the liver segment. Measurements should be taken and the lesions interrogated with color Doppler or power Doppler to check for unusual vascularity or mass effects on adjacent liver parenchyma. Image optimization of liver cysts can be achieved by reduction of the sector width, adjustment of the focal zone to the level of the cyst, write-zoom magnification, and removal of spatial compounding imaging to show the enhanced through-transmission of the ultrasound beam.

The hepatic vasculature should also be interrogated with color and pulsed Doppler. Color flow will give an indication of the direction of flow (which should be toward the liver), and thrombus may be apparent as filling defects (Fig. 66-17). The MPV should be assessed coronally and sagittally with the patient in the left lateral decubitus position. The coronal approach allows visualization of the longitudinal axis of the MPV. Normal portal venous flow is of low velocity toward the liver with a gentle respiratory variation (Fig. 66-18). In portal hypertension, the flow may become “to and fro,” then reversed (Fig. 66-19). The pulsatility of the MPV flow is assessed with spectral Doppler; the mean velocity in the fasted state is between 15 and 18 cm/s, which increases by 50% to 100% after eating.²⁹ The pulsed-wave sample volume is placed within the lumen of the MPV (before it bifurcates into the right and left branches) on a longitudinal view of the MPV without including the vessel wall and ensuring that the Doppler angle between the axis of the MPV and the Doppler beam is always less than 60 degrees. The velocity scale should be adjusted to improve sensitivity. The waveform of normal hepatopetal flow is monophasic flow toward the liver. As portal hypertension develops, the flow may become biphasic (forward flow in systole and reverse flow in diastole), then eventually reverse (hepatofugal).

Hepatofugal MPV flow is indicative of severe portal hypertension, and the common cause of this is liver cirrhosis. If hepatofugal portal vein flow is identified, recanalization of the umbilical vein and other portosystemic shunts may occur, and evidence of this should be sought (Fig. 66-20). The remainder of the abdomen should be examined, looking for splenomegaly and ascites. Hepatofugal flow may alternatively be due to occlusion of the MPV by thrombus or a mass. Multiple small tortuous vessels may be seen around the thrombosed MPV in cavernous transformation of the portal vein.

Figure 66-18 Color and pulsed-wave Doppler examination of the right portal vein showing normal flow.

Figure 66-19 Color and pulsed-wave Doppler examination of the right portal vein showing reversed flow in a patient with cirrhosis and portal hypertension.

The sagittal approach allows the measurement of the diameter of the MPV at the porta hepatis where the MPV enters the liver. This is achieved by positioning the transducer just inferior to the xiphisternum and scanning subcostally. The diameter of the portal vein is measured at the point where it crosses the IVC

Figure 66-20 Dilated recanalized umbilical vein seen on an extended field of view image heading from the liver toward the umbilicus.

Figure 66-21 Fold in the neck of the gallbladder. This may cast a shadow and simulate calculi in the transverse plane.

(i.e., between the intrahepatic portion and the portal confluence). The measurement of the MPV is performed on the B-mode image; the calipers are positioned perpendicular to the vessel to exclude the echogenic portal vein walls and to measure only the portal vein lumen. This is performed while the patient is maintaining gentle respiration. A measurement greater than 13 mm is considered abnormal.³⁰

The hepatic artery should normally not exceed 6 mm in diameter, but it may enlarge in cases of alcoholic hepatitis or cirrhosis.³¹ The hepatic venous flow is normally triphasic, but the waveform may be altered by right-sided heart failure (which may also cause dilation of the veins), or thrombosis may occur. The thrombus may be isoechoic with liver parenchyma and missed unless the hepatic veins are deliberately sought, and color flow may help visualize hypoechoic or isoechoic thrombus. Occlusion of the veins may lead to Budd-Chiari syndrome with the development of congestive hepatopathy.

Gallbladder and Biliary Tract

Ultrasound has long been accepted as an excellent method of examining the gallbladder and the biliary tract.³² It is often performed with examination of the liver and pancreas, but a focused study of the gallbladder and biliary tree is occasionally performed, for example, immediately before elective cholecystectomy to determine the need for bile duct exploration.

The patient should fast before the examination to ensure adequate distention of the gallbladder. A 5-1 MHz curved linear array probe is sufficient for most examinations, but a higher frequency transducer (9-4 MHz) can be used to assess the fundus in some slimmer patients or children. Tissue harmonic imaging may be useful to demonstrate the gallbladder and biliary tree,³³ although care is needed with use of tissue harmonics as it will remove reverberation artifacts from the gallbladder lumen in the near field and may also obscure fine calculi or "sludge." The patient is placed supine initially, although the patient should be rolled into a right anterior oblique or left lateral decubitus position during the course of the examination. This maneuver will help unfold the gallbladder, allowing it to shift from being embedded on the visceral surface of the right

liver lobe to a more accessible midline position. It also allows further assessment of the neck. The movement from supine to left lateral decubitus position will cause any mobile stones or sludge to move into the new gravity-dependent position. Erect positioning should be performed to look for mobile gallstones; it may also be necessary to visualize the distal common bile duct through a water-filled stomach and duodenum. It should also be noted if the patient has any tenderness over the gallbladder during the scan (positive sonographic Murphy's sign).

The transducer is placed in the right midclavicular line in a parasagittal orientation and the long axis of the gallbladder is sought. Long-axis views are supplemented with short-axis views, and the entire gallbladder should be inspected. Suspended inspiration will help move the gallbladder caudally, and intercostal views may be useful. The size, shape, and position of the gallbladder are highly variable, but a diameter of more than 5 cm is considered abnormal and indicates a distended gallbladder. It is commonly pear shaped, with the neck found near the porta hepatis and the fundus in a fossa on the undersurface of the right lobe of the liver; but it may be found in an intrahepatic position or on a mesentery, and the fundus may reach the right iliac fossa, especially in the elderly. The fundus of the gallbladder may be folded (the phrygian cap); maneuvers to unfold the fundus include further fasting to distend the gallbladder and placement of the patient in the left lateral position. The wall is usually thin and uniform, and bile should appear hypoechoic. Particular attention should be paid to the neck of the gallbladder because stones may collect there in the supine position. Failure to demonstrate the gallbladder may be due to prior cholecystectomy, nonfasting state, calculous disease, shadowing or reverberation from the near wall of the gallbladder, or congenital absence of the gallbladder.³⁴

Gallstones will appear as echogenic structures with distal acoustic shadowing. They are highly variable in size and shape and will usually move if the patient is rolled unless they are impacted in the neck of the gallbladder. A higher frequency transducer may be used to look for small stones in a superficial gallbladder. False positives include folds in the wall of the gallbladder, which can be differentiated from stones by turning the transducer through 90 degrees (Fig. 66-21) or by repositioning

the patient, and loops of echogenic bowel indenting the posterior wall of the gallbladder, which on peristalsis may cast a dirty shadow, unlike the clean shadow of a gallstone. A wall-echo-shadow pattern may be seen when a contracted gallbladder is full of calculi³⁵ (Fig. 66-22). Polyps are echogenic but less echogenic than stones; they do not cast distal acoustic shadows and are not mobile. They may be single or multiple, and most are benign. The probability of malignancy increases with the size of the polyp (most malignant polyps are more than 10 mm in diameter), age, and the presence of gallstones and if there are fewer than three polyps.³⁶⁻³⁸

The wall of the gallbladder may be generally thickened (>2 mm) in acute cholecystitis, but this is not a specific sign.³⁹ It may also occur in the postprandial state and in other conditions including ascites, hypoalbuminemia, and hepatitis. Other signs of acute cholecystitis are gallbladder wall edema (Fig. 66-23), positive sonographic Murphy's sign, and pericholecystic

Figure 66-22 The wall-echo-shadow complex seen when a gallbladder full of calculi contracts. This may be confused for an echogenic gas-filled segment of bowel.

Figure 66-23 Transverse view of the gallbladder fundus showing a thickened edematous gallbladder wall.

fluid. Focal gallbladder wall thickening may be seen in adenomyomatosis, gallbladder carcinoma, and metastatic deposits. The gallbladder fills and drains by the cystic duct, which joins the common hepatic duct to form the common bile duct after a variable distance. The exact level at which this occurs is often not visible, and the extrahepatic bile duct may be referred to as the common duct when it is not clear where the cystic duct joins the common hepatic duct to form the common bile duct.

The biliary tree should be examined both within the liver and in the extrahepatic course. Normal intrahepatic bile ducts more peripheral than the left and right hepatic ducts are usually not visualized even with modern equipment. When the intrahepatic bile ducts are dilated, they can be recognized adjacent to the portal venous branches (which are visible even when of normal caliber and can be recognized by their echogenic borders due to the presence of adjacent fat); this appearance has been likened to a double-barreled shotgun.⁴⁰ The dilation may be generalized if the obstruction is central at the porta or distally within the common duct, or it may be localized to a segment or lobe if there is a more proximal obstruction. A more patchy distribution of dilation may be seen where a diffuse process affects the bile ducts, such as diffuse cholangiocarcinoma. An attempt should be made to follow the extrahepatic common duct to the ampulla of Vater if possible. Shadowing from bowel gas may obscure the mid and distal duct, but changing of the patient's position, use of the gallbladder as an acoustic window, or ingestion of water can improve visualization. This is particularly important when proximal dilation of the biliary tract is encountered and the level and cause of the obstruction are sought. Calculi within the distal duct and pancreatic head masses are common causes of distal common bile duct obstruction. The common duct is measured close to the porta just distal to the point at which the right hepatic artery crosses between the portal vein and the duct (Fig. 66-24). The duct then continues in the free edge of the lesser omentum to the head of the pancreas and the sphincter of Oddi, and the diameter of the duct increases in the extrahepatic section before tapering in the head of the pancreas. The normal caliber varies with age but should be less than 5 mm in adults.⁴¹ The duct does dilate with

Figure 66-24 Normal hepatoduodenal ligament anatomy. Normal common duct showing the right hepatic artery crossing between the common hepatic duct (anterior) and the portal vein (posterior).

age, and the upper limit of normal should be increased to 8 mm in the elderly. If the patient has a dilated duct before cholecystectomy, the duct may not return to normal diameter postoperatively, and a diameter of up to 10 mm may be considered normal after cholecystectomy.^{42,43}

Pancreas

Ultrasound examination of the pancreas can be a useful technique,⁴⁴ but views of the pancreas can be limited by overlying bowel gas. Improved views may be obtained by displacing gas-filled loops of bowel by pressure, sitting the patient up, or administering gasless fluid and scanning the pancreas through the fluid-filled stomach. The pancreas has an oblique transverse lie and is divided into the head (including the uncinate process), the neck, the body, and the tail. The head is situated to the right of the midline in the C of the duodenum. The uncinate process passes posteriorly and medially behind the superior mesenteric vein (Fig. 66-25). The neck of the pancreas connects the body to the tail anterior to the superior mesenteric artery and vein. The body then passes transversely and slightly cranially, and the tail ends in the splenic hilum. For the whole organ to be adequately assessed, the curvilinear 5-1 MHz transducer is positioned obliquely from the left upper quadrant to the right iliac fossa, inferior to the xiphisternum (Fig. 66-26). Sweeping the transducer cranially, then caudally will allow a full assessment of the head and uncinate process to check for masses, focal changes in echotexture, prominent lymph nodes, and any peripancreatic fluid. The tortuous splenic artery passes along the superior margin of the pancreas, whereas the splenic vein follows a straight course posterior to the gland and is a useful landmark. The splenic vein joins the superior mesenteric vein to form the portal vein posterior to the neck; the uncinate process may pass posterior to this junction. The normal outline of the pancreas is slightly lobular, and if the echogenicity of the gland is compared with the liver parenchyma, it is normally slightly more echogenic than the liver; but obviously care must be taken if the echogenicity of the liver is abnormal, for example, in fatty infiltration. The pancreas may also become more echogenic with fatty infiltration. The uncinate process

and the posterior part of the head may be relatively hypoechoic (Fig. 66-27), and this should not be confused with a tumor.⁴⁵ The main pancreatic duct may be visualized in normal individuals, but the diameter in the head should not exceed 3 mm. Dilation of the duct should prompt a search for an obstructing lesion.

Acute pancreatitis is a common condition often associated with gallstones or a history of alcohol use. There may be no abnormalities on ultrasound or CT for 24 to 48 hours. Areas of the gland then become swollen and edematous, manifested by hypoechoic areas on ultrasound. The duct can be obstructed by the swelling, leading to ductal dilation. Fluid collections may be seen in the peripancreatic retroperitoneal space or in the lesser sac. A search should always be made for gallstones as a treatable cause of pancreatitis, and elective cholecystectomy after the pancreatitis has resolved may prevent further episodes. Complications of pancreatitis include pseudocyst and pseudoaneurysm formation. Chronic pancreatitis may produce an enlarged

Figure 66-26 Transverse view of normal pancreas. The probe has been angled obliquely to include the tail of the pancreas, which passes laterally and cranially.

Figure 66-25 Normal pancreas. Transverse view of the pancreas illustrating the normal uncinate process (U) passing posterior to the superior mesenteric vein.

Figure 66-27 Hypoechoic uncinate process of the pancreas. This is a normal variant seen in up to 25% of patients.

Figure 66-28 Left basal pleural effusion seen above the diaphragm. There is also some ascites adjacent to the spleen.

Figure 66-29 Splenomegaly in a patient with cirrhosis and portal hypertension. Note also the dilated splenic vein branches at the splenic hilum.

gland in the early stages; in the later stages, shrinkage, calcifications, and increased echogenicity are more common. Duct strictures and dilations are seen, often with calculi, and are characteristic of the disease but are better demonstrated with pancreatography.

Pancreatic adenocarcinoma most commonly arises in the head and may cause dilation of the common bile duct and the pancreatic duct. The tumors are typically hypoechoic but attenuating and can be detected when they are as small as 1 cm in diameter. Endoscopic or intraoperative ultrasound may be used to improve lesion detection and characterization. The reduced need for penetration enables the use of higher frequencies and hence better resolution. Other tumors found in the pancreas include intraductal papillary mucinous tumors and endocrine tumors (of which insulinoma is the most common).

Spleen

The spleen is well protected by the lower left ribs, and this can pose a challenge to the ultrasonographer. The patient is placed in the right posterior oblique or right lateral decubitus position, and the spleen is scanned from the subcostal or intercostal approach. The spleen moves caudally on inspiration, and often this movement can be used to achieve a thorough examination of the entire spleen through a single intercostal space by a combination of breathing instructions to the patient and a sweeping movement of the transducer. The subphrenic space above the spleen should be examined for collections, and a left pleural effusion can often be seen above the diaphragm (Fig. 66-28). The spleen moves anterior to the left kidney on inspiration, a fact that should be borne in mind when attempting to establish the origin of a mass in the left upper quadrant.

The echotexture of the spleen is homogeneous; it is normally slightly hyperechoic compared with the kidney and isoechoic with the liver. The outer surface is smooth and convex, whereas the visceral surface is concave and may show indentations for the adjacent organs. The splenic artery and vein enter and leave

the spleen at the hilum, which is found on the visceral surface. Accessory spleens are common (10% of subjects in autopsy series) and are often seen in the region of the hilum or within the lienorenal ligament or the gastrosplenic ligament. They are rounded or oval, measuring 1 to 2 cm in diameter, and isoechoic with spleen.⁴⁶ Vessels can often be traced from the splenic artery and vein to the accessory spleen.⁴⁷ It is important to differentiate accessory spleens from lymph nodes or masses; in patients undergoing splenectomy for hematologic disease, the presence of accessory spleens should be carefully documented before surgery. On occasion, the spleen may have a long vascular pedicle and is described as wandering.⁴⁸ It may then be found in locations other than the left upper quadrant and is prone to torsion.

Assessment of splenic size by physical examination is inaccurate and requests for evaluation with imaging are common. A single ultrasonic measurement of splenic length has been shown to be an accurate predictor of splenic volume,⁴⁹ and ultrasound is cheaper and more accessible than CT scanning without the risks of ionizing radiation. The longitudinal diameter of the spleen should measure less than 11 cm.⁵⁰ There are many causes of diffuse splenic enlargement, including infection, liver disease, portal hypertension, lymphoma and other metastatic and primary neoplasms, hematopoietic disease, and splenic vein thrombosis (Fig. 66-29).

Ultrasound may be used to detect free fluid in an unstable trauma patient, and although large splenic lacerations may be visible, the sensitivity of ultrasound to splenic injuries (even with the use of contrast agents) is unacceptably low.⁵¹ CT is the investigation of choice in the acute setting. In the nontraumatic setting, focal splenic lesions are divided into cystic and solid lesions. Cystic lesions may be congenital, infectious (echinococcal), or secondary to trauma. Solid lesions may be benign or malignant. Splenic hemangiomas and hamartomas can be differentiated by the presence of vascular flow on Doppler imaging. Infarcts are typically peripheral, wedge shaped, and hypoechoic in the acute stage but later may become hyperechoic. Common malignant solid lesions include primary lymphoma and metastases. These are typically hypoechoic.^{52,53}

Summary

Magnetic resonance imaging (MRI) is frequently used as a problem-solving tool for the evaluation of disease processes throughout the body and is a powerful imaging modality to characterize disease in the solid abdominal organs. With widespread availability, technologic advances, and increasing familiarity of ordering physicians and radiologists alike, MRI is becoming the modality of choice for parenchymal lesion detection, anatomic localization, and lesion characterization. MRI has high spatial and temporal resolution without exposure to ionizing radiation, allowing accurate imaging on a wide spectrum of patients, including pregnant women and children.

Various technologic advances in MRI have been made in recent years, including increased magnetic strength, improved coil technology, and advanced imaging sequences. The purpose of this chapter is to discuss commonly used imaging sequences and protocols as well as recent developments in advanced sequences in MRI of the abdomen. An all-encompassing summary of each pathologic diagnosis in the abdomen is beyond the scope of this chapter; the chapter reviews solid abdominal organ lesions and pathologic processes in which MRI is crucial for accurate diagnosis and characterization.

Magnetic Resonance Imaging Technique

FIELD STRENGTH

Of the recent advances in MRI, the most significant is the increasing magnetic field strength. The most common field strengths in clinical use in MRI are 1.5T and 3.0T. Higher magnetic field strengths allow increased longitudinal magnetization and signal intensity, resulting in increased signal-to-noise ratio

(SNR). The resulting increased SNR can be used to increase spatial resolution or to decrease imaging acquisition time, allowing improved imaging.

There are disadvantages to higher magnetic field strengths. Higher purchasing prices in addition to higher maintenance prices are among the disadvantages. Reduced T1 contrast secondary to lengthening of T1 is a limitation of higher magnetic field strengths. Increased susceptibility from magnetic field inhomogeneity, patient motion, and chemical shift are also a disadvantage of higher magnetic field strengths.

SURFACE COILS

For imaging of the abdomen, the goal is to maximize SNR for a large area of interest, and a multichannel phased-array body coil is typically used. Flexible coils are used to maintain the contour of the torso, which allows high-resolution imaging of the abdomen and pelvis. Phased-array coils allow parallel imaging, in which each channel has its own receiver, and the multichannel system increases the number of receiver coils. Advances in phased-array coil technology have resulted in increased SNR and improved image quality, faster scan time, and larger scan area.

Other body parts, such as the rectum or the female pelvis, can be imaged with a phased-array body coil that covers a smaller field of view with high-resolution images. Intraluminal coils are also used to image pelvic organs such as the prostate gland, yielding images with high SNR and high resolution. Anatomy, extracapsular extension, perivascular invasion, and lymphadenopathy can be readily assessed by MRI of the prostate.

MAGNETIC RESONANCE SEQUENCES

The basic MR sequences employed in imaging of solid abdominal organs are fairly standard. These include axial and coronal T2-weighted images with and without fat suppression, diffusion-weighted images with apparent diffusion coefficient (ADC) maps, in- and out-of-phase gradient-echo images, and dynamic contrast-enhanced three-dimensional T1 gradient-echo images with fat saturation. Two- and three-dimensional free-breathing navigator-triggered magnetic resonance cholangiopancreatography (MRCP) sequences may also be obtained if clinically indicated. Additional sequences, such as balanced fast field echo or fast imaging employing steady-state acquisition sequences, can be obtained for evaluation of vascular anatomy, delineation of bowel and mesentery, and quantification of fat by T2*.

Single-shot T2-weighted images are rapidly acquired, heavily T2-weighted images that are useful for evaluating fluid and structures with short T2 values. The benefit of this sequence is

the speed with which images are acquired; however, the contrast-to-noise ratio is not as high as in other T2-weighted fast spin-echo sequences. Axial T2 fast spin-echo sequences with fat suppression have the benefit of increased liver-to-spleen contrast and are useful for detection of lesions. Lymph nodes are also easily detected on this sequence. PROPELLER (periodically rotated overlapping parallel lines with enhanced reconstruction) is a fast imaging technique whereby a fraction of k space is acquired in each frame. Each imaging acquisition in a PROPELLER sequence acquires a rectangular portion of k space, with each acquisition acquiring images through the k space center, and can reduce artifact from respiratory motion (Fig. 67-1). Other T2-weighted sequences, such as the three-dimensional turbo spin-echo sequence known as SPACE (sampling perfection with application-optimized contrast with different flip-angle evolutions), have been developed to decrease image acquisition times. With this sequence, the acquired images serve as a data set that can be used to create postprocessed reformatted images in axial, coronal, and sagittal planes. The SPACE sequence decreases the number of T2-weighted image acquisitions and can potentially replace two-dimensional T2-weighted images.

Diffusion-weighted imaging with varying diffusion gradient strengths has become important for evaluating malignant neoplasms and inflammatory conditions.¹ The principle of diffusion-weighted imaging is based on random motion of microscopic water molecules and diffusion of water in body tissues. Diffusion of water molecules is based on cell membrane integrity and tissue cellularity. Diffusion-weighted imaging provides functional information about tissue cellularity along with the ADC values, which are calculated from diffusion-weighted imaging data. An increase in the number of cells in conditions such as primary malignant neoplasms, metastases, and infection or abscesses leads to crowding of extracellular spaces and further restriction of water molecules.

T1-weighted in-phase and opposed-phase gradient-echo images are useful for detection of focal and diffuse hepatic steatosis, but the T2* effects and susceptibility artifact are also useful components of this sequence. There is signal loss on the opposed-phase images at water-fat interfaces, resulting in the India ink artifact or fat-water cancellation artifact, whereby a sharply defined black rim is seen at water-fat interfaces. Water and fat protons precess at different frequencies, and in spin-echo sequences, a 180-degree refocusing pulse causes the protons to be in phase when the echo is acquired; however, gradient-echo images lack the 180-degree refocusing pulse. Focal and diffuse hepatic steatosis is manifested as loss of signal

on the opposed-phase images (Fig. 67-2). The dual gradient-echo images also provide information by T2* effects, whereby hepatic parenchymal storage diseases, such as hemochromatosis and hemosiderosis, decrease in signal intensity with the longer time to echo secondary to continued transverse magnetization decay (Fig. 67-2). Susceptibility artifacts result from field inhomogeneities occurring at interfaces of materials with varying magnetic susceptibility, such as metallic objects, gas-filled bowel, and pneumobilia (Fig. 67-3). The difference in precession rates of fat and water protons is proportional to the magnetic field strength and is 3.5 ppm or 225 Hz at 1.5T. At 3T, the difference in precession rates is 450 Hz, and the protons are out of phase at 1.1 ms, 3.4 ms, 5.6 ms, and so forth, whereas the protons are in phase at 2.2 ms, 4.5 ms, 6.7 ms, and so forth. Acquiring the out-of-phase image at a short time interval of 1.1 ms followed by the in-phase image at 2.2 ms can be challenging, and the second- or third-order echo may need to be obtained. The DIXON method uses the T1 in-phase and out-of-phase images to mathematically calculate “fat-only” and “water-only” images, which is particularly useful in areas with high magnetic susceptibility (Fig. 67-4).

Dynamic contrast-enhanced three-dimensional T1-weighted gradient-echo images with fat saturation sequences are helpful in assessing for the presence of enhancement as well as characteristic enhancement patterns of certain lesions. Dynamic imaging with arterial, portal venous, equilibrium, and delayed phases is useful for evaluation of all upper abdominal organs, including the liver, spleen, pancreas, adrenal glands, and kidneys. Images are performed with a breath hold of approximately 15 to 20 seconds. Subtraction images are obtained by subtracting the images made before the administration of gadolinium from the dynamic contrast-enhanced images and are helpful in assessing for the presence and degree of enhancement.

Two- and three-dimensional free-breathing navigator-triggered MRCP sequences have excellent spatial and temporal resolution. Accurate assessment of the hepatobiliary and pancreatic ducts with MRCP has replaced endoscopic retrograde cholangiopancreatography (ERCP) and percutaneous transhepatic cholangiography as the initial study of choice in the evaluation of hepatobiliary and pancreatic ducts.

MAGNETIC RESONANCE CONTRAST AGENTS

Multiple MR contrast agents are currently in use. They can be categorized into five classes: extracellular, hepatobiliary, reticuloendothelial, blood pool, and combined agents.²⁻⁶ A complete list and thorough review of the mechanism of action and side

Figure 67-1 Respiratory motion artifact. **A.** Axial T2 image with fat saturation is degraded secondary to respiratory motion. **B.** Rapid acquisition PROPELLER technique reduces artifact from respiratory motion.

Figure 67-2 Hepatic steatosis and hemochromatosis. Axial gradient-echo in-phase (A) and opposed-phase (B) images show loss of signal intensity on the opposed-phase image, consistent with hepatic steatosis. The liver lesion in the left lobe is a hemangioma with surrounding focal fatty sparing. In a different patient, axial in-phase (C) and opposed-phase (D) images demonstrate decreased signal on the in-phase images, with the longer echo time reflecting the T2* shortening in a patient with hemochromatosis.

Figure 67-3 MR susceptibility artifacts. Axial CT with intravenous administration of contrast material (A) demonstrates surgical clips in the right lobe of the liver from a prior wedge resection. Susceptibility artifact from the surgical clips is seen as low intensity on the axial opposed-phase image (B); it "blooms" and is exaggerated in size on the in-phase image (C) with the longer echo time.

Figure 67-4 DIXON sequence. Axial T1 in-phase image (A) demonstrates an oval area in segments IV and V that decreases in signal on the opposed-phase image (B), consistent with focal fat. On the axial fat-only image (C), the focal fat is hyperintense relative to liver parenchyma compared with low signal on the water-only image (D).

effects are beyond the scope of this chapter; however, the indications for and MR techniques used to enhance these agents are briefly reviewed.

Extracellular agents such as gadopentetate dimeglumine (Magnevist) have been in use for the longest time clinically. These agents are distributed in the extracellular space; 20 mL is administered and nearly entirely excreted by the kidneys.⁶

Hepatobiliary agents such as gadoxetic acid (Eovist) are taken up by hepatocytes and excreted through the biliary system, which causes the liver, biliary ducts, and hepatocyte-containing lesions to be T1 hyperintense.³⁻⁶ The average dose is 0.025 mmol/kg for approximately 10 mL, and there is around 50% hepatic and 50% renal excretion. The delayed hepatobiliary phase ranges from 10 minutes to hours, which is significantly shorter compared with the combined agent gadobenate dimeglumine (MultiHance).⁶

Blood pool agents stay intravascular for a longer time compared with the extravascular agents and are used for angiography.^{2,3} Although use of blood pool agents is limited in imaging of solid abdominal organs, it is listed here for completeness.

Combined agents have extracellular, blood pool, and hepatobiliary characteristics. Gadobenate dimeglumine (MultiHance) is taken up by hepatocytes, and 5% of the administered dose is excreted in bile; the remaining 95% is excreted renally. A limitation of this agent is that the hepatobiliary phase occurs approximately 1 to 2 hours after ingestion of the contrast agent, which is significantly longer compared with hepatobiliary agents.^{2,6}

Imaging of Abdominal Organs

A complete summary of each pathologic diagnosis in the abdomen is beyond the scope of this chapter, and as such, this

chapter reviews solid abdominal organ lesions for which classic MRI characteristics are diagnostic. MRI features are crucial for narrowing the differential diagnosis and making accurate diagnoses.

LIVER

The three most common benign hepatic lesions encountered are cavernous hemangiomas, focal nodular hyperplasia (FNH), and hepatic adenomas. FNH and adenomas share imaging characteristics but can be accurately differentiated by various MR sequences and contrast agents. FNH can also be differentiated from fibrolamellar hepatocellular carcinoma (HCC) on the basis of MR characteristics.

Cavernous Hemangiomas

Cavernous hemangiomas, the most common primary liver tumor, occur in 20% of the general population.⁷⁻⁹ On histologic examination, hemangiomas are composed of large blood-filled vascular channels of varying sizes and shapes.⁷ Typically, they are solitary and small; however, multiplicity can occur, and giant cavernous hemangiomas can be larger than 20 cm. On imaging, hemangiomas have characteristic appearances. On ultrasound (US), hemangiomas are focal, homogeneous, and echogenic and can have varying appearances, depending on the degree of background hepatic steatosis, which can be easily assessed on MRI. MRI shows typical features of hemangiomas, which include T1 hypointensity and marked T2 hyperintensity; on the dynamic contrast-enhanced images, hemangiomas have peripheral nodular enhancement with progression in a centripetal distribution (Fig. 67-5).⁷⁻⁹ Flash-filling hemangiomas can be seen, in which the entire lesion homogeneously enhances in the arterial phase. In addition, the very bright T2 hyperintense

Figure 67-5 Hepatic hemangioma. Axial arterial phase image (A) illustrates a hypointense lesion in segment II with peripheral nodular and discontinuous enhancement that progressively fills on portal venous (B) and 3-minute delayed (C) images consistent with a hemangioma.

signal has a high sensitivity (100%) and specificity (92%) for differentiation of hemangiomas from hepatic metastases.

Focal Nodular Hyperplasia

FNH is the second most common benign hepatic tumor after hemangiomas. It is an aggregate of hepatocytes that form in response to a “central scar,” which represents an underlying vascular malformation or clusters of blood vessels and bile ducts.⁷⁻¹⁰ FNH is hypointense to isointense on T1-weighted images and isointense to mildly hyperintense on T2-weighted images with a T2 hyperintense scar.⁷⁻⁹ After the administration of gadolinium, there is brisk, homogeneous, and intense arterial enhancement of the lesion with the exception of the central scar, which has gradual delayed enhancement (Fig. 67-6).

Approximately 20% of FNH cases are atypical and do not have characteristic imaging features.⁷ The three subtypes include telangiectatic FNH, FNH with cytologic atypia, and mixed hyperplastic and adenomatous FNH, all of which do not possess the central vascular malformation and are often challenging to diagnose on imaging.^{7,9} These three nonclassic FNH types have bile ducts and some degree of normal hepatocytes, allowing uptake and excretion of hepatobiliary contrast agents.

The delayed enhancement of the central scar helps differentiate FNH from fibrolamellar HCC, which is an uncommon type of HCC. Fibrolamellar HCC usually is manifested as a large heterogeneous T1 hypointense and T2 hyperintense mass, and a majority (80%) of fibrolamellar HCCs contain a true central scar (Fig. 67-7).⁹ In contradistinction to FNH, the central scar is a true scar that is T2 hypointense and demonstrates minimal or no enhancement after gadolinium administration.⁹

Hepatic Adenoma

Hepatic adenomas are rare benign tumors containing well-differentiated hepatocytes with few or no biliary ducts. Most adenomas are single, and 90% of adenomas occur in women. On the basis of recent pathologic and genetic evaluation of hepatic adenomas, four subtypes of adenomas have been developed: inflammatory hepatocellular adenoma, hepatocyte nuclear factor 1 α (HNF-1 α)–mutated hepatocellular adenoma, β -catenin–mutated hepatocellular adenoma, and unclassified.^{8,11-14} Each type should be considered a different entity because imaging appearances as well as management options vary according to the subtype.

Inflammatory adenomas were previously known as telangiectatic adenomas or telangiectatic FNH. This subtype commonly occurs in young women taking oral contraceptive medications and obese patients. On MRI, inflammatory adenomas are T1 isointense to mildly hyperintense and T2 diffusely intense to hyperintense. T1-weighted in-phase and opposed-phase gradient-echo images show little or no loss of signal. After the administration of gadolinium, inflammatory adenomas enhance on the arterial phase and persist on the portal venous and delayed phases (Fig. 67-8).⁸ Two complications of hepatic adenomas are intratumoral bleeding and development of HCC. Bleeding occurs in 25% to 50% of adenomas, and tumors larger than 5 cm are at increased risk for bleeding and rupture. Inflammatory adenomas have the highest risk of bleeding of all subtypes.

HNF-1 α –mutated hepatocellular adenoma accounts for 30% to 35% of all adenomas and is the second most common subtype. This subtype occurs almost exclusively in women, with

Figure 67-6 Focal nodular hyperplasia. Axial T2 fat-saturated image (**A**) demonstrates a T2 isointense lesion with a central T2 hyperintense "scar." After the administration of gadolinium, axial fat-saturated images in 25-second (**B**), 70-second (**C**), and hepatobiliary (**D**) delayed phases show brisk, homogeneous, and intense arterial enhancement of the lesion with the liver parenchyma.

Figure 67-7 Fibrolamellar hepatocellular carcinoma. Axial T2 fat-saturated image (**A**) shows a mildly T2 hyperintense lesion that is large and with a true central scar. Axial dynamic images after the administration of gadolinium (**B-D**) show early heterogeneous arterial enhancement with minimal or no enhancement of the true central scar.

Figure 67-8 Inflammatory hepatic adenoma. Axial T2 fat-saturated image (A) shows a T2 hyperintense lesion in segment VI, which enhances on the arterial phase (B) and persists on the 180-second delayed phase (C).

the majority of patients taking oral contraceptive medications. Estrogens in these medications have been postulated to cause somatic mutations in HNF-1 α adenomas, and inactivation of *HNF1A* gene results in nonfunctioning HNF-1 α protein, which subsequently promotes proliferation of hepatocytes and lipogenesis with impaired fatty acid regulation in hepatocytes, resulting in fat deposition within the hepatocytes. On MRI, HNF-1 α -mutated hepatocellular adenomas are T1 hyperintense to isointense and T2 isointense to slightly hyperintense; after the administration of contrast material, there is moderate arterial enhancement with no persistent portal venous or delayed phase enhancement.⁸ Diffuse signal loss on out-of-phase gradient recalled echo images is seen because of intracellular steatosis, with sensitivity and specificity as high as 85% and 100%, respectively. HNF-1 α -mutated hepatocellular adenomas, even lesions larger than 5 cm, have minimal risk of bleeding, and there is minimal or no risk for development of HCC.

β -Catenin-mutated hepatocellular adenoma accounts for 10% to 15% of all adenomas. This subtype occurs more commonly in men and is associated with exogenous testosterone use, familial adenomatous polyposis, and glycogen storage disease. There is overexpression of the glutamate-ammonia lipase gene, resulting in elevated levels of glutamine synthetase, which has been used recently in immunohistochemical analysis for definitive diagnosis. This subtype has homogeneous or heterogeneous T1 and T2 hyperintense signal, depending on the presence of blood and necrosis. These lesions enhance intensely on the arterial phase, with variable persistence on the portal venous and delayed phases. The imaging appearance can be confused with that of HCC. This subtype has the highest risk of malignant transformation, with an overall risk of 5% to 10%

as the β -catenin pathway is involved in the pathogenesis of HCC. Other risk factors for malignant transformation are male sex, glycogen storage disease, tumors larger than 5 cm, and exogenous anabolic steroid use.

Focal and Diffuse Steatosis

Various manifestations of fatty infiltration include focal, patchy, and diffuse.^{15,16} Focal fat deposition and focal fat sparing can be mistaken for a focal hepatic lesion.¹⁵ MRI is helpful in differentiating a true hepatic lesion from focal fat deposition and focal fat sparing, particularly the T1-weighted in-phase and opposed-phase gradient-echo images. Focal fat deposition is lower in intensity on the opposed-phase images compared with the in-phase images and has high signal on the DIXON fat-only images (see Fig. 67-4). In contradistinction, focal fat sparing does not decrease in intensity on the opposed-phase images but instead appears hyperintense relative to the surrounding hepatic steatosis.

Another helpful differentiating imaging feature is the location, which typically is in the gallbladder fossa, in the medial aspect of the left hepatic lobe, along the falciform ligament, and in the central aspect of segment IV.¹⁵ Also, no mass effect is seen on adjacent structures or hepatic parenchyma, and blood vessels course through areas of focal hepatic steatosis and focal fat sparing. The presence of normal enhancing liver is helpful in accurate diagnosis of focal fat and focal fat sparing.

Diffuse hepatic steatosis involves a majority of the hepatic parenchyma, and on MRI, the liver intensity decreases on the opposed-phase images relative to the in-phase images (see Fig. 67-2A, B).^{15,16} Rather than appearing as focal hepatic signal abnormality, the entire hepatic parenchyma is diffusely involved.

Cholangiocellular Origin Lesions

MRI is extremely helpful in diagnosing and characterizing lesions of cholangiocellular origin, including simple hepatic cysts, biliary hamartomas, peribiliary cysts, biliary cystadenoma, and biliary cystadenocarcinoma.⁷ MRCP sequences are useful to assess the relationship of these lesions to the biliary tree.

Simple hepatic cysts are lined by biliary epithelium and originate from precursor microhamartomas.⁷ Cysts are usually round, well defined, and larger than 1 cm, and they can be single or multiple. Multiple simple hepatic cysts may be seen in adult polycystic kidney disease. On MRI, simple hepatic cysts have classic imaging characteristics with T1 hypointensity, T2 hyperintensity, and no associated enhancement.

Biliary hamartomas are also known as von Meyenburg complexes. They represent rare benign malformations of the biliary system secondary to failed involution of embryonic biliary ducts.⁷ Hamartomas are usually numerous, subcentimeter, well-defined T1 hypointense, T2 hyperintense, nonenhancing lesions with no connection to the biliary tree (Fig. 67-9A).

Peribiliary cysts are benign cystic dilations of obstructed glands around the biliary duct walls.⁷ Inflammation and disturbed periportal circulation lead to gland obstruction and result in peribiliary cyst formation. These lesions are typically associated with cirrhosis with portal hypertension and portal vein thrombosis. Peribiliary cysts are usually multiple T1 hypointense, T2 hyperintense tubular structures coursing along the bile ducts (Fig. 67-9B). They typically have smooth walls with no internal components, and they do not communicate with the biliary system.

Biliary cystadenoma, a rare benign cystic neoplasm, is a precursor to the malignant form of biliary cystadenocarcinoma.^{7,17} A majority of these lesions originate from the intrahepatic bile

ducts and are complex, multiloculated, cystic masses with enhancing internal septations (Fig. 67-9C). The MRI findings are variable, depending on the internal composition of the lesion, specifically if the lesion is composed of mucinous or serous fluid. The presence of enhancing nodular septations in the lesion is suggestive of the malignant biliary cystadenocarcinoma. These tumors tend to recur after complete surgical excision, and biliary cystadenomas can undergo malignant degeneration even after years of stability.

Cirrhosis and Hepatocellular Carcinoma

Cirrhosis is associated in up to 90% of patients with HCC and is characterized by irreversible disruption of the normal hepatic architecture with fibrosis and hepatic nodules.^{6,18-23} The most common causes of cirrhosis worldwide, in order of decreasing frequency, are hepatitis C virus, hepatitis B virus, alcohol, and nonalcoholic steatohepatitis; in the United States and Europe, the most common cause of cirrhosis is alcohol. Hepatitis B and C increase the risk of HCC 20 times, and the rate of HCC development once a diagnosis of cirrhosis is made is 1% to 4% per year.

The development of HCC is a multistep continuous carcinogenic process whereby multiple alterations lead to malignant transformation of the hepatocyte.^{6,18-23} The hepatocarcinogenesis has been arbitrarily divided for diagnostic and practical purposes. There are two types of hepatocellular nodules, regenerative and dysplastic nodules. Regenerative nodules result from proliferation of hepatocytes and supporting stroma, leading to nodular transformation of hepatic parenchyma with no fibrous septations between the nodules. These nodules can be mononodular or multinodular and can also be micronodular (<3 mm) or macronodular (>3 mm). Dysplastic nodules result from hepatocyte proliferation with abnormal growth or dysplasia,

Figure 67-9 MR spectrum of biliary disease.

A. Single maximum intensity projection MRCP image shows numerous, subcentimeter, well-defined T1 hypointense, T2 hyperintense, nonenhancing lesions with no connection to the biliary tree consistent with biliary hamartomas. **B.** Maximum intensity projection MRCP image in a different patient illustrates cystic lesions coursing along the bile ducts in a patient with cirrhosis consistent with peribiliary cysts. **C.** Coronal T2 image in a third patient shows a complex, multiloculated, cystic mass; a mucinous cystadenoma was confirmed on surgical resection.

with derangement of normal architecture and cellular atypia. HCC is a malignant neoplasm with hepatocellular differentiation and development of neoangiogenesis with progressive loss of portal venous blood flow and increased arterial vascularity.

Cirrhosis on imaging is characterized by atrophy and hypertrophy of certain segments, liver contours, presence of hepatic nodules, fibrotic and fatty changes, and signs of portal hypertension. The right lobe of the liver and the medial segment of the left hepatic lobe (segment IV) atrophy, whereas the caudate and lateral segments of the left hepatic lobe (segments II and III) hypertrophy. The liver contour tends to be nodular, although this may not be apparent in all cirrhotics, and there is widening of the fissures between lobes and segments. Regenerative nodules are seen, and diffuse lacelike bands of fibrosis may be present; diffuse or geographic areas of fatty change have also been seen in cirrhosis. Signs of portal hypertension, including splenomegaly, enlargement of the portal vein, presence of varices (gastric, splenic, esophageal, caput medusae), and peribiliary cysts, are present in varying degrees in cirrhotic patients.

MRI has revolutionized the diagnostic and treatment implications involved in the care of cirrhotic patients.¹⁸⁻²² MRI can accurately characterize cirrhosis-associated liver nodules, with the critical role being early detection of HCC. The MRI examination is easily and accurately reproducible, allowing staging of HCC, planning of treatment options, and assessment of response to treatment. HCC is T2 hyperintense with avid arterial enhancement that shows washout or becomes hypointense relative to the surrounding liver on the delayed phase (Fig. 67-10).

Regenerative nodules are T1 variable, T2 hypointense, and after the administration of gadolinium, these nodules are usually isointense to surrounding parenchyma as they maintain

hepatocellular function. Dysplastic nodules have variable imaging appearances that overlap with both regenerative nodules and HCC. Low-grade dysplastic nodules are usually T2 hypointense, in contradistinction to high-grade dysplastic nodules, which have high signal on T2. Low- and high-grade dysplastic nodules have variable T1 signal intensity but usually have T1 high signal. Also, low-grade dysplastic nodules share enhancement patterns with regenerative nodules, and high-grade dysplastic nodules share enhancement patterns with HCC, but low- and high-grade dysplastic nodules typically enhance as much as hepatic parenchyma. Siderotic nodules are characterized by high iron content and can be either regenerative or dysplastic nodules. On MRI, siderotic nodules are low T1 and T2 because of magnetic susceptibility from local field inhomogeneities. It is difficult to differentiate regenerative siderotic nodules from dysplastic siderotic nodules on imaging.

A dysplastic nodule may contain a focus of HCC and have a nodule-in-nodule appearance. The dysplastic nodule has low T2 signal, and after the administration of gadolinium, a focus of arterial enhancement is visualized, resulting in the so-called nodule-in-nodule appearance. HCC appearance on MRI depends on the size and grade of the malignant neoplasm. Small HCCs are less than 2 cm and are classified into early and progressed categories. Early HCCs are T1 hyperintense and T2 hypointense to isointense with relative hypoenhancement on the arterial phase but are hypointense on the portal venous phase. The arterial hypovascularity is thought to be secondary to decreased portal venous vascularity but insufficient arterial supply. The use of hepatobiliary contrast agents increases the detection of these early HCCs, in which normal hepatocytes will have enhancement, whereas the HCC will not enhance and will be hypointense. However, well-differentiated early HCCs may have residual hepatocyte function and have uptake of contrast

Figure 67-10 Hepatocellular carcinoma.

Coronal T2 image (A) illustrates a 3.5-cm mildly T2 hyperintense lesion in segment VI of the liver that enhances on the arterial phase (B) and has washout on the portal venous phase (C) with pseudocapsular enhancement.

material, with false-negative results. Progressed HCCs are less of a diagnostic dilemma in that they are well-defined, small T1 isointense and T2 moderately hyperintense nodular lesions with avid arterial enhancement and washout on the portal venous and delayed phases. On the basis of the new Organ Procurement and Transplantation Network policy for liver transplantation, small HCCs can be diagnosed on imaging alone if the lesion is at least 1 cm and less than 2 cm with arterial enhancement and washout on portal venous or delayed phase and has peripheral rim enhancement. Large lesions between 2 and 5 cm must have arterial enhancement and either washout on portal venous or delayed phase or peripheral rim enhancement or growth by 50% or more on serial imaging less than 6 months apart.

Iron Depositional Disease

Hemochromatosis can be primary, originating from a genetic disorder causing increased intestinal absorption of iron, or secondary, which is related to transfusions or chronic disease. Iron is normally stored in hepatocytes and in the reticuloendothelial cells, but excess iron can act as a catalyst of hydrogen peroxide into free radicals, resulting in cellular damage. MRI can noninvasively quantify the amount of iron in the liver and assess for response to treatment with high sensitivity and specificity.²⁴⁻²⁷ Primary hemochromatosis follows a hepatic parenchymal deposition pattern whereby iron is deposited in hepatocytes, then spread to the remainder of the liver, pancreas, thyroid, and cardiac tissue. Secondary hemochromatosis follows a reticuloendothelial deposition pattern whereby cells of the reticuloendothelial system of the liver, bone marrow, and spleen accumulate iron. Because the iron is not deposited in the hepatocytes, there is no associated tissue damage with secondary hemochromatosis. In advanced cases of secondary hemochromatosis, the iron deposition may exceed the storage capacity of the reticuloendothelial cells and may result in parenchymal deposition.

Hemochromatosis can be accurately and quickly diagnosed with MRI because of the shortening of T1 and T2 as well as the T2* shortening due to field inhomogeneities caused by superparamagnetic effects of iron.²⁴⁻²⁷ On T1-weighted in-phase and opposed-phase gradient-echo images, there is diffuse decreased intensity on images with the longer echo time, which is usually the in-phase images on 1.5T MRI (see Fig. 67-2C, D). This effect is due to the increased sensitivity to field inhomogeneities on the longer echo time sequence from increased T2* effect. Iron quantification can readily be performed with MRI with a high degree of accuracy on routine T1-weighted in-phase and opposed-phase gradient-echo images and T2* imaging.^{24,25}

BILE DUCTS AND GALLBLADDER

US is the initial imaging study of choice in the evaluation of gallbladder disease because of the high sensitivity and specificity. However, there are limitations of US, including operator dependence and degradation of image quality in obese patients. An increasing role of MRI has evolved with improved technology and faster acquisition times whereby MRI is a valuable imaging complement to US and computed tomography (CT).²⁸⁻³¹ MRI provides a comprehensive and detailed assessment of the biliary tree, including anatomic evaluation as well as disease processes, and is an established alternative to ERCP.²⁸⁻³¹

Cholelithiasis and Choledocholithiasis

Cholelithiasis is the concretion of bile in the biliary system, of which there are two types: cholesterol stones (75%-80%) and pigmented stones (20%-25%). Gallstones can form from cholesterol supersaturation; risk factors include obesity, pregnancy, rapid weight loss, high-fat diet, female gender, and advanced age. Gallstones can also form secondary to decreased gallbladder motility, which leads to crystallization of bile and predisposes to stone formation; risk factors include rapid weight loss, use of total parenteral nutrition, pregnancy, and oral contraceptive use. Pigmented stones can be of the black stone variety, which is caused by increased unconjugated bilirubin from chronic hemolytic states, or brown stones, which are associated with recurrent cholangitis or parasitic infections.

Stones within the intrahepatic and extrahepatic biliary tree can be primary, which form within the biliary ducts, or secondary, whereby stones from the gallbladder migrate into the common bile duct. Predisposing factors of primary choledocholithiasis include parasitic infections or recurrent cholangitis, congenital abnormalities, and prior surgery.

MRI accurately and consistently detects gallstones, which are best appreciated on T2-weighted images, where they appear as multiple filling defects in a gallbladder filled with T2 hyperintense bile.^{28,30} MRI can also differentiate the types of gallstones because both cholesterol and pigmented stones are T2 hypointense; however, pigmented stones are higher in T1 signal compared with cholesterol stones, and they also have a larger range of signal intensities.³⁰ MRI and MRCP heavily T2-weighted sequences also detect choledocholithiasis with a high sensitivity and specificity (>95%); the stones are seen as filling defects within the bile ducts (Fig. 67-11).²⁸⁻³³

Acute Cholecystitis

Acute cholecystitis is one of the most common causes of hospital admission from the emergency department and is the most common complication of cholelithiasis; up to 95% of cases are associated with gallstones. US is the traditional imaging modality of choice for gallbladder disease in patients thought to have acute cholecystitis. MRI is increasingly used in the emergency setting, given the faster acquisition sequences and improved technology. Imaging of suspected cases of acute cholecystitis assists in planning of immediate or delayed cholecystectomy and of the surgical approach (laparoscopic or open). MRI is particularly useful in clinically and sonographically equivocal cases of acute cholecystitis, with sensitivities up to 95% and specificities up to 89%,²⁹ and in the assessment of the bile ducts for possible choledocholithiasis. MRI and MRCP performed within 24 hours of arrival to the emergency department provide additional information in the evaluation of acute biliary disease, particularly with equivocal or inconclusive sonographic findings.²⁹ MRI has a sensitivity of 95% and specificity of 90% for diagnosis of acute cholecystitis.

MRI findings of uncomplicated acute cholecystitis include the presence of a gallstone usually impacted in the gallbladder neck or cystic duct, gallbladder distention (transverse diameter >4 cm), wall thickening (>3 mm), abnormal T2 hyperintense mural thickening and edematous stratification, wall hyperemia, and pericholecystic fluid.²⁸⁻³¹ MRI has excellent tissue contrast that increases the detection of gallbladder wall edema and pericholecystic fluid, which is manifested as T2 hyperintensity around the gallbladder (Fig. 67-12). A highly specific sign

Figure 67-11 Cholelithiasis and choledocholithiasis. Coronal MRCP image (A) shows multiple filling defects within the gallbladder and bile ducts, which were confirmed at ERCP (B).

Figure 67-12 Acute cholecystitis. Coronal T2 (A) and axial T2 with fat saturation (B) images show mild gallbladder wall thickening and pericholecystic fluid. After the administration of gadolinium, axial fat-saturated image (C) demonstrates hyperemia in the gallbladder fossa (arrow).

(specificity of 70%) for acute cholecystitis is transient enhancement of the pericholecystic liver parenchyma seen immediately after the administration of gadolinium; this is thought to be secondary to reactive hyperemia of the hepatic parenchyma surrounding the acutely inflamed gallbladder.

Complications of acute cholecystitis are seen in up to 40% of cases and include gallbladder perforation with pericholecystic abscess formation, gangrenous cholecystitis, emphysematous cholecystitis, hemorrhagic cholecystitis, and perforation with bilioenteric fistula formation.^{30,31} Most complications can

be readily identified by MRI with the exception of emphysematous cholecystitis, for which CT is the best imaging modality to detect air within the gallbladder lumen and wall.

Gallbladder Carcinoma

Gallbladder malignant disease is the most common biliary tree carcinoma and the fifth most common gastrointestinal neoplasm.^{30,34} The prognosis is poor, with an estimated patient survival time of 3 months after diagnosis and a 5% 5-year survival rate.³⁴ At the time of initial presentation, there is usually

advanced disease with infiltration into the adjacent liver parenchyma and lymph node metastases. The thin gallbladder wall and the continuity of the connective tissue around the gallbladder with that of the liver allow invasion of the hepatic parenchyma and lymphatics. A majority of the cases (approximately 90%) are associated with gallstones, probably secondary to chronic inflammation; other risk factors include porcelain gallbladder and long common pancreatic-biliary channel.

Focal or diffuse gallbladder wall thickening of more than 1 cm is seen in early gallbladder malignant disease; however, the typical imaging appearance is an infiltrating mass in the gallbladder fossa. The mass is T1 isointense to hypointense and T2 heterogeneously hyperintense compared with adjacent liver, which enhances after the administration of gadolinium. Intrahepatic biliary dilation, best seen on MRCP images, may be seen secondary to hepatic duct compression directly by the tumor, direct invasion by the tumor, or lymphadenopathy, and MRCP images are helpful in localizing the site of obstruction. In cases in which the gallbladder is indistinct and replaced diffusely with neoplasm, the presence of gallstones within the mass can be helpful in making the diagnosis (Fig. 67-13).

In 25% of cases, an intraluminal polypoid mass is confined to the muscle layer. These cases are associated with a better prognosis compared with the diffusely infiltrating pattern of malignant disease. The polypoid masses are T1 isointense, T2 hyperintense compared with liver, and the mass projects into the gallbladder lumen. After the administration of gadolinium, the polypoid masses enhance early with prolonged enhancement.

Cholangiocarcinoma

Cholangiocarcinoma, a primary malignant neoplasm arising from the biliary epithelium, is the second most common primary hepatic tumor after HCC.^{35,36} The peak age prevalence is in the sixth to seventh decades; risk factors include choledochal cysts, primary sclerosing cholangitis, familial polyposis, chronic infection, and congenital hepatic fibrosis. Most cases (95% of cases) are histologically adenocarcinoma. Cholangiocarcinoma can be anatomically classified as intrahepatic, including central and peripheral, or extrahepatic.^{35,36} Central intrahepatic cholangiocarcinoma arises from the hepatic duct bifurcation and proximal common hepatic duct, whereas peripheral intrahepatic tumors involve the second-order bile ducts. Tumor growth has been described as polypoid

(intraductal), infiltrative (periductal), or exophytic (mass forming); infiltrating central intrahepatic tumors (Klatskin tumors) have been subclassified according to the Bismuth-Corlette classification.

On MRI, mass-forming cholangiocarcinomas are T1 hypointense to isointense and have variable T2 signal, depending on the amount of tumoral fibrosis, hemorrhage, and necrosis. After gadolinium administration, the masses have little arterial enhancement with increased progressive enhancement on the delayed phases owing to the presence of fibrosis and central tumoral necrosis and desmoplastic response (Fig. 67-14). Smaller tumors may demonstrate homogeneous and avid arterial enhancement that persists on subsequent phases because of the absence of fibrosis. Intraductal tumors are T1 hypointense to isointense with mild T2 hyperintensity with heterogeneous enhancement. On MRCP sequences, the area of biliary ductal narrowing with upstream ductal dilation can be readily detected to localize and to characterize the tumor.

PANCREAS

MRI is a valuable imaging tool to assess a wide spectrum of pancreatic disease.^{37,38} Specific morphologic features and signal intensity characteristics allow diagnosis of pathologic processes such as acute and chronic pancreatitis, adenocarcinoma, neuroendocrine tumors, microcystic and macrocystic cystadenoma, serous cystadenoma, intraductal papillary mucinous neoplasms, and solid pseudopapillary neoplasms (or solid and papillary epithelial neoplasms). Ductal anatomy and pathologic processes can be readily assessed on MRCP with sensitivity similar to that of ERCP. The pancreas has inherent high signal on T1-weighted images and enhances maximally during the pancreatic arterial phase around 15 to 20 seconds, subsequently becoming isointense on later dynamic contrast-enhanced images.

Acute Pancreatitis

Acute pancreatitis is an acute inflammatory process involving the pancreatic parenchyma and surrounding organs. The diagnosis is made by clinical and laboratory findings; however, imaging is used to confirm the diagnosis and to detect complications. CT is the most common imaging modality used, but MRI has an increasing role, particularly because patients with acute pancreatitis tend to be younger and require multiple

Figure 67-13 Gallbladder adenocarcinoma. Coronal CT (A) and axial post-gadolinium fat-saturated (B) images demonstrate a large heterogeneous mass originating in the gallbladder fossa. Calcified gallstones within the center of the mass are seen on the CT image.

Figure 67-14 Cholangiocarcinoma. Axial arterial (A) and portal venous (B) phase images after the administration of gadolinium show a mass in the atrophied right lobe of the liver with associated biliary dilation and capsular retraction. The mass enhances minimally on the arterial phase, with progressively increasing enhancement on the portal venous phase.

examinations.³⁸⁻⁴² Moreover, advances in MRI technology allow excellent pancreatic imaging and detection of associated complications, such as necrosis, fluid collections, and vascular complications including thrombi and pseudoaneurysms.³⁹⁻⁴¹ Causes of acute pancreatitis include alcohol, gallstones, metabolic abnormalities, infection, trauma, and medications.

Anatomic variations of the pancreatic duct, including pancreas divisum and a long common pancreatic-biliary channel, have been associated with acute pancreatitis⁴² and can readily be assessed with MRCP. Pancreas divisum is the most common congenital anomaly; the ventral and dorsal pancreatic buds do not fuse, and the ventral duct (duct of Wirsung) drains the ventral anlage and the dorsal duct (duct of Santorini) drains a majority of the pancreas, which empties into the minor papilla. Pancreas divisum is detected on MRCP with high sensitivity and specificity. The presence of a long common channel (>15 mm) allows reflux of bile into the pancreatic duct, resulting in acute pancreatitis.

Typical MRI findings of acute pancreatitis are focal or diffuse enlargement of the pancreas with heterogeneous areas of low T1 signal and high T2 signal and normal homogeneous or slightly heterogeneous enhancement.³⁷⁻⁴⁰ Peripancreatic stranding in mild acute pancreatitis is best seen on T1 as peripancreatic hypointensity; in more severe pancreatitis, T2-weighted images show peripancreatic T2 hyperintensity.³⁷⁻⁴⁰

Necrotizing pancreatitis occurs in 20% to 30% of cases and increases the mortality associated with acute pancreatitis. There are three types according to the revised Atlanta classification system: pancreatic parenchymal necrosis, peripancreatic necrosis, and combined pancreatic parenchymal necrosis with peripancreatic necrosis; these types can be sterile or infected. Assessment of the extent of necrosis is important as there is a correlation with overall prognosis. Areas of necrosis on T2 sequences are low intensity, but when liquefied, necrosis is T2 hyperintense. Necrosis is best depicted on post-gadolinium images as areas of decreased enhancement.

Pancreatic and peripancreatic collections can be seen in acute pancreatitis.^{39,40} Acute collections are classified as acute pancreatic fluid collection (APFC) if there is no necrosis or acute necrotizing collection (ANC) if necrosis is present. With time, after 4 weeks, acute pancreatitis without necrosis and APFC are associated with pseudocysts, whereas pancreatic

necrosis and ANC are associated with walled-off necrosis. On MRI, APFC has liquefied components and conforms to anatomic boundaries around the pancreas with no discernible wall, which are T1 hypointense and T2 hyperintense. With time, APFC may develop into pseudocysts, which are unilocular encapsulated fluid collections with T1 hypointensity and T2 hyperintensity. ANC is a persistent collection of fluid and necrotic material that replaces pancreatic parenchyma after necrotizing pancreatitis. ANC over time develops into walled-off necrosis, which is heterogeneous on MRI due to the presence of nonliquefied necrotic pancreatic parenchyma and necrotic fat.

Vascular complications of acute pancreatitis include venous thrombus formation and pseudoaneurysms. Venous thrombi are the most common vascular complication of acute pancreatitis and affect the splenic, superior mesenteric, and portal veins; on MRI, thrombi are best seen on post-gadolinium images. Pseudoaneurysms are caused by blood vessel wall weakening from the proteolytic enzymes and most frequently involve the splenic, pancreaticoduodenal, and gastroduodenal arteries. Pseudoaneurysms are readily detected on post-gadolinium images and opacify during the early arterial phase. Pseudoaneurysms can rupture, with resulting peripancreatic hemorrhagic fluid collections that are high signal on T1 due to methemoglobin with a T2 hypointense hemosiderin rim. MRI has the benefit of persistent signal abnormalities compared with CT.

Pancreatic Cystic Lesions

Accurate characterization of pancreatic cystic lesions is crucial to create a differential diagnosis and to guide subsequent treatment, and MRI has been shown to be the optimal imaging modality for complete assessment.⁴³ Pancreatic cystic lesions can be primary, such as pseudocysts, serous cystadenomas, and mucinous lesions, including mucinous cystadenoma, cystadenocarcinoma, and intraductal papillary mucinous neoplasms; or they can be cystic changes in a solid neoplasm, including adenocarcinoma, neuroendocrine tumors, and solid pseudopapillary neoplasms (or solid and papillary epithelial neoplasms).⁴³⁻⁴⁶

Serous cystadenomas are benign cystic neoplasms composed of numerous small cysts, typically less than 1 cm, that are

separated by fibrous septa radiating from a central scar.⁴⁵ These neoplasms occur in older women, typically older than 65 years, and are typically incidentally found. On MRI, these lesions appear as a cluster of small T2 hyperintense cysts with thin enhancing fibrous septa separating the cysts; a central calcified scar with signal void may be seen. There is no connection to the main pancreatic duct (Fig. 67-15).^{43,45}

Mucinous cystadenomas are thick-walled, uniloculated or multiloculated cystic masses in the pancreatic body or tail that are lined by mucin-producing columnar epithelium with no communication to the pancreatic ducts. Most are incidentally found in women. Mucinous cystadenomas have malignant potential and are surgically resected.⁴³ On MRI, these lesions are uniloculated or multiloculated, with signal intensity that follows simple fluid despite the presence of mucin, and are T1 hypointense and T2 hyperintense, although intrinsic T1 hyperintense signal has been described (Fig. 67-16).⁴³ The thick wall has enhancement in the delayed phases because of the presence of fibrosis, and the internal septa enhance. Intracystic nodular soft tissue components suggest the presence of invasive carcinomatous components. Mucinous cystadenocarcinomas have intracystic nodular soft tissue components in a mucinous cyst with surrounding ovarian-type stroma.

Intraductal papillary mucinous neoplasms (IPMNs) are mucin-producing tumors arising from the epithelial lining of the main or side branch pancreatic ducts.⁴³ The pancreatic ductal epithelial cells are transformed into neoplastic mucin, producing cells that form papillary projections, and the excess mucin results in cystic dilation of the ducts (Fig. 67-17). At ERCP, spillage of mucin into the ampulla of Vater is classically

seen.⁴³ An association between IPMN and concomitant pancreatic ductal adenocarcinoma and pancreatic ductal adenocarcinoma arising from IPMN has been described, both of which are thought to have favorable biologic behavior or to be diagnosed at an earlier stage.^{43,47,48} IPMNs are classified as involved with the main pancreatic duct or isolated to the side branch ducts, which has important implications because 60% to 70% of main duct IPMNs have invasive carcinoma, as opposed to 20% of side branch IPMNs containing invasive carcinoma.^{43,49} MRI is the imaging modality of choice in the evaluation of IPMNs to determine the location and type of the lesion. Main duct IPMNs have focal or diffuse enlargement of the main pancreatic duct, and although chronic pancreatitis can be manifested with diffuse enlargement of the pancreatic duct, helpful differentiating imaging features are associated parenchymal changes in chronic pancreatitis with T1 hypointensity and delayed contrast uptake secondary to fibrosis. Multiple dilated side branch T2 hyperintensities are seen in side branch IPMNs. Enhancing and nodular soft tissue components in IPMNs are suggestive of concomitant adenocarcinoma, which can arise from the IPMN or at a different site along the pancreatic duct.

Pancreatic Solid Lesions

Solid pancreatic lesions include pancreatic adenocarcinoma, neuroendocrine tumors, solid pseudopapillary neoplasms (or solid and papillary epithelial neoplasms), and metastases, all of which have different appearances on MRI. As described previously, these masses may have cystic components from tumor degeneration.

Figure 67-15 Pancreatic serous cystadenoma. Axial T2 fat-saturated MR image (A) demonstrates a cluster of small T2 hyperintense cysts with thin septations. No communication or dilation of the main pancreatic duct is visualized on the maximum intensity projection MRCP image (B).

Figure 67-16 Pancreatic mucinous cystadenoma. Axial post-gadolinium fat-saturated (A) and axial T2 (B) images show a lobulated T1 hypointense and T2 hyperintense lesion in the pancreatic tail. There are thick-walled septations, which enhance.

Pancreatic Adenocarcinoma

Pancreatic adenocarcinoma is the most common malignant neoplasm of the pancreas and arises from the ductal epithelium. Pancreatic adenocarcinoma carries a very poor prognosis with a 5-year survival rate of approximately 6%.^{50,51} It is often locally progressed at the time of diagnosis.

The normal pancreatic parenchyma is T1 hyperintense; however, adenocarcinoma will appear as an irregular T1 hypointense mass relative to normal pancreas on T1-weighted fat-suppressed images because of an intense fibrotic, desmoplastic reaction. After the administration of contrast material, adenocarcinomas usually have less enhancement on the arterial phase and occasionally demonstrate delayed enhancement. Diffusion-weighted imaging and ADC reconstruction maps are particularly helpful in detecting small adenocarcinomas as pancreatic adenocarcinomas exhibit restricted diffusion, probably attributable to the associated fibrosis, with high signal on diffusion-weighted imaging with associated low ADC values.⁵² Pancreatic ductal abrupt obstruction with upstream dilation is commonly seen, which can be readily assessed on MRCP images, and the common bile duct is usually dilated with an abrupt termination, resulting in the so-called double duct sign.

Figure 67-17 Mixed main and side branch IPMN. Maximum intensity projection MRCP image demonstrates a multilobulated cystic mass in the uncinate process that has a direct connection to the main pancreatic duct, which is dilated.

Neuroendocrine Neoplasms

Pancreatic neuroendocrine neoplasms are rare; neuroendocrine carcinoma accounts for 1% to 2% of all pancreatic tumors, but the incidence has increased as a result of increased detection.⁵³ Pancreatic neuroendocrine neoplasms are tumors that arise from neuroendocrine cells and include a range of tumors. They can be functioning or nonfunctioning; the two most common types are insulinomas and gastrinomas. Functioning tumors tend to be small at presentation, in contradistinction to nonfunctioning tumors, which are larger with possible venous invasion and metastatic lesions. Like adenocarcinoma, these lesions have low signal intensity on T1-weighted fat-suppressed images. Lesions are hyperintense on T2 with hyperenhancement on the arterial phase, which is one of the typical MRI features. Preoperative MRI assists in accurate diagnosis and may be helpful in determining tumor stage and grade.⁵³

Solid Pseudopapillary Neoplasms

Solid pseudopapillary neoplasms are rare, accounting for 1% of all pancreatic neoplasms, and have a low malignant potential.⁴³ They typically occur in young women (average age of 30 years). On imaging, these lesions are well-defined, heterogeneous, large masses with central cystic areas of T2 hyperintensity from tumor degeneration. These masses can be completely solid with mild T2 high signal, whereas masses that are mostly cystic are T2 hyperintense. Thick enhancing capsule of enhancing soft tissue is usually seen on post-gadolinium images.

ADRENAL GLANDS

The most valuable MRI sequence in imaging of the adrenal glands is chemical shift T1-weighted in-phase and opposed-phase gradient-echo imaging. This sequence is particularly useful in determining the presence of fat within adrenal lesions. Fat-containing adrenal masses can be classified into two groups: lesions with intravoxel fat, such as adenomas; and lesions with macroscopic fat, such as myelolipomas.⁵⁴ Pheochromocytomas have typical MRI characteristics, but not all lesions have diagnostic features.

Adrenal Adenoma

Adrenal adenomas are the most common lesions found in the adrenal glands.⁵⁴ The presence of intracellular fat is diagnostic of adrenal adenomas, and this can be accurately detected on the opposed-phase gradient-echo image (Fig. 67-18).^{54,55} A 20%

Figure 67-18 Bilateral adrenal adenomas. Axial T1 in-phase image (A) shows bilateral adrenal nodules that decrease in signal on the opposed-phase sequence (B), consistent with fat-containing adenomas.

decrease in signal intensity on the opposed-phase image compared with the in-phase image is diagnostic of an adrenal adenoma. Adenomas typically have homogeneous enhancement in the early arterial phase with more than 50% washout on the delayed phase images.

Myelolipoma

Myelolipomas are rare benign tumors of the adrenal gland and account for 7% to 15% of incidentally found adrenal masses.⁵⁴ Myelolipomas are composed of adipocytes and hematopoietic tissue (myeloid and erythroid cells) and are non-functioning.^{54,56} A tumor with a major fat component is found on diagnostic MRI, and on the basis of the MR appearances, myelolipomas can be categorized into three main categories.⁵⁶ Myelolipomas can be homogeneous and T1 hyperintense with intermediate T2 signal, suggestive of a large fat component; heterogeneous mass with T1 hyperintense foci, corresponding to foci of fat, and T2 hyperintense foci, which have mixed fat and myeloid components; and nodules that are T1 hypointense and T2 hyperintense compared with liver, corresponding to lesions composed of predominantly myeloid components. Adrenal myelolipomas rarely spontaneously rupture, resulting in hemorrhage.

Pheochromocytoma

Pheochromocytomas are tumors arising from chromaffin cells of the adrenal medulla. Most pheochromocytomas, approximately 90%, arise from the adrenal gland; the remaining 10% of lesions are extra-adrenal and arise along the sympathetic chain. On MRI, pheochromocytomas are intensely T2 hyperintense, the so-called light bulb sign, and enhance intensely. Approximately 33% of pheochromocytomas do not have the light bulb sign and instead are heterogeneous on T2-weighted images. Pheochromocytomas are the tumors with the “rule of 10s” or the “10% tumor”; 10% are extra-adrenal, 10% are familial, 10% are malignant, 10% are bilateral, and 10% occur in children.

KIDNEYS

MRI is helpful in diagnosis, in assessing enhancement of renal lesions, and in determining the presence of intralesional fat.⁵⁷ Different lesions in the kidneys, including cysts, angiomyolipoma, oncocytoma, renal cell carcinoma (RCC), and transitional cell carcinoma (TCC), have characteristic MRI findings.^{57,58}

Renal Cysts

Renal cysts are common and are present in 20% to 30% of the middle-aged adult population. Simple renal cysts are round, homogeneously hypointense on T1 and T2 hyperintense, with imperceptible walls that do not enhance. Complicated cysts can be hemorrhagic, infected, or proteinaceous, which would alter the signal characteristics accordingly.

Angiomyolipoma

Angiomyolipomas are benign renal tumors composed of blood vessels, smooth muscle, and fatty components and are the most common benign renal tumor; 90% of angiomyolipomas are unilateral and single, whereas the remaining 10% are multiple and bilateral and associated with tuberous sclerosis complex. A renal mass containing fat on imaging is diagnostic of an angiomyolipoma; however, 5% do not have detectable fat. On MRI, these lesions follow fat signal on all sequences, and the most reliable method of detecting bulk fat is to compare images before and after application of a fat-suppressed pulse sequence (Fig. 67-19).

Oncocytoma

Oncocytoma is a benign renal tumor composed of eosinophilic epithelial cells arising from collecting ducts; it is the second most common benign renal tumor next to angiomyolipoma. A central stellate fibrosis with compressed blood vessels is known as the central scar and is seen in approximately half of the cases. These lesions are T1 isointense to hypointense and slightly T2 hyperintense compared with renal cortex. The central scar is manifested as a stellate area of low T1 intensity and high T2 signal.

Renal Cell Carcinoma

RCC is a malignant tumor of the renal tubular epithelium. It projects from the cortical surface and deforms the renal cortex (Fig. 67-20). The subtypes of RCC include clear cell (70%), papillary (10%-15%), granular cell (7%), chromophobe cell (5%), sarcomatoid (2%), and collecting duct (<1%). MRI appearances vary by the subtype, but the most common, clear cell, has T1 isointense signal relative to renal parenchyma with increased T2 signal. Clear cell RCC has areas of low signal on opposed-phase images indicating the presence of fat, which is seen in 60% of tumors. Marked enhancement in viable areas of tumor is seen. Papillary RCC is the second most common subtype and has

Figure 67-19 Bilateral renal angiomyolipoma. Axial T1 images without (A) and with fat saturation (B) show bilateral small T1 hyperintense lesions that drop in signal on the fat-saturated sequences, confirming the presence of intralésional fat.

Figure 67-20 Renal cell carcinoma. Axial T2 image (A) illustrates a large exophytic heterogeneous T2 isointense lesion in the upper pole of the right kidney. On the axial (B) and coronal (C) post-gadolinium images, an intraluminal thrombus is visualized extending from the right renal vein into the inferior vena cava.

Figure 67-21 Bladder transitional cell carcinoma. Axial T2 (A) and axial T1 post-gadolinium (B) images show a large, homogeneously enhancing T2 heterogeneous mass arising from the left side of the bladder, extending toward the left pelvic side wall, and closely approximating the left external iliac artery and vein.

low T2 signal with low levels of enhancement after gadolinium administration.

Transitional Cell Carcinoma

TCC most commonly occurs in the bladder but accounts for 90% of all tumors arising from the urothelium lining the renal pelvis. Of the two subtypes, papillary and nonpapillary, papillary TCC is more common. TCC tends to be multifocal and can involve the entire collecting system. TCC is T1 isointense to the renal medulla and can infiltrate the renal sinus; it is seen as a filling defect on T2-weighted images because of the high signal T2 intensity of urine (Fig. 67-21). TCCs are hypoenhancing

masses, but avid enhancement may occur, and a focal filling defect that has enhancement is highly suggestive of a TCC. MRI is also helpful in assessing renal vein or inferior vena cava tumor extension.

Summary

MRI is a commonly used imaging modality, particularly in the evaluation of solid abdominal organs. With the increasing use of MRI, familiarity with imaging sequences and technique is imperative. In addition, knowledge of and familiarity with typical MRI features of various solid organ pathologic processes are crucial.

In this chapter, we discuss fluorine-18-deoxyglucose positron emission tomography (FDG PET) and positron emission tomography/computed tomography (PET/CT) of the solid parenchymal organs of the abdomen and highlight in particular the advantages and pitfalls of hepatopancreatobiliary, splenic, and adrenal PET imaging.

Gallbladder and Biliary Tract

The gallbladder and biliary tract are essentially indistinguishable from the liver because of minimal physiologic FDG activity in these structures.

CHOLANGIOCARCINOMA

Several studies have shown that FDG PET has a 90% or greater sensitivity for primary cholangiocarcinoma.¹⁻⁴ However, the accuracy of FDG PET for detection of cholangiocarcinoma

appears to be dependent on the anatomic location, growth pattern, and pathologic characteristics. Studies have shown that the sensitivity of FDG PET for detection of intrahepatic cholangiocarcinoma is relatively higher than that for perihilar and extrahepatic tumors (Fig. 68-1). For example, Corvera and associates⁵ found that the sensitivity of PET for detecting intrahepatic cholangiocarcinoma was 95% compared with only 69% for extrahepatic cholangiocarcinoma. Petrowsky and colleagues⁶ and Lee and coworkers⁷ also found that the sensitivity for detecting intrahepatic cholangiocarcinoma was higher than that for extrahepatic cholangiocarcinoma (93% vs 55% and 100% vs 78%, respectively). Furthermore, Moon and colleagues⁴ found that the site of the primary tumor affected sensitivity of FDG PET; the sensitivity of FDG PET was lower for perihilar tumors compared with intrahepatic and common bile duct cancers (83% vs 91%, 91%). Moreover, in cases of perihilar tumors, the sensitivity of PET was lower than that of CT (83% vs 92%). Yamada and coworkers⁸ also concluded that the sensitivity for the detection of hilar cholangiocarcinomas was less than that for the detection of intrahepatic and extrahepatic cholangiocarcinoma (78% vs 100% and 84%, respectively). However, Reinhardt and associates⁹ were able to differentiate 12 patients with extrahepatic cholangiocarcinoma from 8 patients without cholangiocarcinoma by PET/CT with a delayed timing of FDG uptake and a maximum standardized uptake value (SUV_{max}) cutoff of 3.6.

The diagnostic accuracy of FDG PET in cholangiocarcinoma is also related to the growth pattern of the tumor. Anderson and coworkers¹⁰ reported a sensitivity of 85% for nodular morphology but only 18% for infiltrating morphology. Kato and associates¹¹ similarly found that 11 of 13 tumors (85%) found to be a tumoral mass in the bile duct on CT were identified on PET, whereas only 4 of 11 infiltrating-type tumors (36%) were detected by PET. The diagnostic accuracy of FDG PET may also differ on the basis of the histopathologic findings. Fritscher-Ravens and coworkers¹² found that whereas all true-positive PET results were seen in the tubular type of cholangiocarcinoma with a high amount of tumor cells and only low production of mucus, false-negative PET results were observed in three patients with mucinous adenocarcinoma.

Cholangiocarcinoma is a well-documented malignant complication of primary sclerosing cholangitis (PSC). The average prevalence of cholangiocarcinoma in PSC is approximately 10%.¹³ The detection of cholangiocarcinoma in patients with PSC remains challenging, despite improvements in morphologic imaging. Alkhawaldeh and colleagues¹⁴ found that by using the SUV_{max} cutoff of more than 3.9 in patients with PSC

Figure 68-1 Cholangiocarcinoma. **A.** Contrast-enhanced CT demonstrates an ill-defined area of low attenuation in the right lobe of the liver (arrow). Note is also made of a biliary stent. **B.** This area demonstrates increased FDG avidity on PET/CT (arrow). Cholangiocarcinoma was confirmed on biopsy.

and suspected cholangiocarcinoma, FDG PET/CT had a sensitivity, specificity, and accuracy of 94%, 83%, and 91%, respectively. However, an earlier study by Fevery and coworkers¹⁵ found that PET is not reliable in the diagnosis of cholangiocarcinoma in patients with PSC as there were two false-positive and one false-negative results in the 10 patients in their study.

The resectability of cholangiocarcinoma depends on its regional and distant spread. Advances in surgery have increased the likelihood of achieving local disease control. Accurate staging is critical for surgical planning and also to prevent unnecessary surgical intervention in those with advanced disease. Compared with CT, PET has been found to have a higher specificity but lower sensitivity in the diagnosis of regional lymph node metastases.^{6,11,16,17} Another study found that FDG PET could detect lymph node metastases undetected by CT and changed the treatment plan in a significant number of cases.⁴ With regard to distant metastases, several studies have demonstrated the high accuracy of FDG PET in the detection of unsuspected distant metastasis.^{4,10,17,18} This revealing of otherwise undetected distant metastases has also been shown to play a significant role in clinical decision-making.

For the detection of recurrent cholangiocarcinoma, PET/CT may be beneficial in detecting disease recurrence for which anatomic imaging can be limited because of distortion and fibrotic changes after surgery. Jadvar and colleagues¹⁹ assessed the role of PET/CT in detecting recurrence after surgery and found a sensitivity and specificity of 94% and 100% for PET/CT compared with 82% and 43% for CT alone.

PET/CT may have a role in predicting survival in patients with cholangiocarcinoma undergoing treatment. Zhu and associates²⁰ found that a decrease in SUV_{max} after treatment of advanced biliary tract cancers with combined gemcitabine, oxaliplatin, and bevacizumab was associated with disease control and an increase in progression-free and overall survival. Furthermore, Haug and coworkers²¹ found that changes in SUV_{max} , SUV_{mean} , and metabolically active tumor volume at 3 months after yttrium 90 (⁹⁰Y) radioembolization for intrahepatic cholangiocarcinoma were able to predict patient outcome.

GALLBLADDER CARCINOMA

FDG PET has been found useful in the characterization of gallbladder lesions (Fig. 68-2). Koh and associates,²² in a study

of 16 patients, found that FDG PET had a sensitivity of 68% and a specificity of 88%. In another case series of 16 patients by Rodriguez-Fernandez and coworkers,²³ in which SUV in the gallbladder of more than 2.5 was considered positive for neoplasm, FDG PET was found to have a sensitivity of 80% and a specificity of 82%. In a study by Oe and colleagues,²⁴ PET had a sensitivity of 75% and a specificity of 100% in distinguishing between malignant and benign gallbladder wall thickening.

Nishiyama and coworkers²⁵ found that delayed FDG PET was more helpful than early FDG PET for evaluating malignant lesions because of increased lesion uptake and increased lesion-to-background contrast. When a threshold of SUV_{early} of 4.5, $SUV_{delayed}$ of 2.9, and retention index of -8 were chosen as arbitrary cutoffs for differentiating between malignant and benign conditions, sensitivity increased from 83% to 96% and 100% for delayed imaging and combined early and delayed imaging, respectively. However, few centers perform delayed FDG PET scanning, in large part because of workflow logistics.

Lee and coworkers⁷ found that in 16 patients with gallbladder cancer, PET/CT detected 14 cases (88%), whereas multidetector CT identified 15 cases (94%). In a study by Corvera and associates,⁵ FDG PET/CT identified 100% of the 15 primary gallbladder carcinomas left in situ. In a study by Petrowsky and colleagues,⁶ PET/CT detected each primary or recurrent gallbladder cancer (100%), whereas contrast-enhanced CT identified tumor in only 10 of 14 patients (71%).

In patients diagnosed with incidental gallbladder cancer after cholecystectomy for presumed benign disease, PET/CT may be a useful tool for the selection of patients for potentially curative treatment and may help reduce the number of patients undergoing nontherapeutic reexploration.^{26,27}

The presence of distant metastases in biliary tract cancers is associated with poor survival, regardless of treatment. It is therefore important to detect distant metastases so that surgery is offered only to those who may benefit from it. A study by Albazaz and colleagues¹⁸ on the clinical impact of FDG PET/CT in management decisions found that PET/CT had a major impact on management in 39% of cases in patients with gallbladder cancer, including upstaging of 27% of the scans performed for initial staging. Corvera and associates⁵ also found that among patients with gallbladder cancer,

Figure 68-2 Gallbladder carcinoma. **A.** Contrast-enhanced CT demonstrates focal thickening of the inferior wall of the gallbladder (arrow). **B.** This region demonstrated increased FDG avidity on PET (arrow), without evidence of distant metastases. This was confirmed as gallbladder carcinoma on surgical resection.

PET changed management in 23% by showing metastatic disease not seen on other imaging, preventing futile and unnecessary explorations.

FDG PET/CT has a role to play in the detection of recurrent gallbladder carcinoma. Kumar and colleagues²⁸ found that FDG PET/CT had a sensitivity of 98% and a specificity of 90% in detecting tumor recurrence. They also concluded that when comparable conventional imaging (contrast-enhanced CT, MRI) was available, PET/CT had a better sensitivity for the detection of recurrence.

Interestingly, FDG PET/CT may also have a role in risk stratification of patients with gallbladder polyps. A study by Lee and colleagues²⁹ found that visual grading, polyp SUV_{max} cutoff of 2.14, and polyp-to-liver ratio cutoff of 1.14 yielded accuracy of 80%, 78%, and 84%, respectively, in diagnosis of malignant gallbladder polyps in the 1- to 2-cm size range.

PITFALLS

FDG PET must be interpreted carefully in patients with PSC and patients with other biliary strictures as biliary stents, known granulomatous disease, or other benign inflammatory conditions may accumulate FDG. In the cases of gallbladder cancer, false-positive FDG PET results have been reported with

xanthogranulomatous cholecystitis,²² tuberculoid granulomatosis of the gallbladder,²³ and adenomyomatosis.^{23,30}

Liver

At the standard image acquisition of approximately 1 hour after FDG administration, hepatic activity is usually mildly intense with a relatively uniformly mottled appearance.

HEPATOCELLULAR CARCINOMA

Well-differentiated hepatocellular carcinoma (HCC) has a high level of glucose-6-phosphatase, which results in dephosphorylation of FDG-6-phosphate and thus low FDG accumulation compared with poorly differentiated HCC, which has a low level of glucose-6-phosphatase and tends to be FDG avid.³¹ Because of the variable glucose metabolism of HCC, FDG PET has shown mixed utility in the detection of HCC. Initial studies on PET-only scanners reported a detection rate of primary untreated HCC of 50% to 70%.³¹⁻³³ A more recent study on PET/CT for the detection of primary HCC reported a sensitivity of 61%.³⁴ The investigators also found that advanced tumor stage, portal vein thrombosis, large tumors, and multiple tumors were significantly associated with positive FDG PET/CT results. With

respect to the size of the lesion, the sensitivity was 27%, 48%, and 93% for index lesions measuring 1 to 2 cm, 2 to 5 cm, and more than 5 cm, respectively.

Even though the sensitivity of FDG PET has been found to be lower than that of other imaging modalities, it still plays an important role in management and prognosis. The detection of extrahepatic metastases, although rare, can significantly affect management. Kawaoka and associates³⁵ compared the efficacy of PET/CT with CT for the detection of extrahepatic metastases (lung, lymph node, and bone) and found that CT was more sensitive than PET/CT for the detection of lung metastases and performed equally well for nodal metastases; however, bone metastases were more accurately detected by PET/CT. The three PET false-negative lung metastases in the study were less than 8 mm. Sugiyama and coworkers³⁶ found a similar pattern, in which the detection rate of FDG PET was 83% for extrahepatic metastases larger than 1 cm but only 13% for lesions of 1 cm or less.

Shiomi and coworkers³⁷ found that the SUV ratio (SUV ratio of tumor to nontumor in the liver) correlated with tumor volume doubling time and that the cumulative survival rate could be predicted on the basis of the SUV ratio. Kawamura and associates³⁸ also found that the SUV ratio was associated with survival, with people with SUV ratio of more than 1.6 having a lower survival rate. Another study found that patients with tumor SUV of more than 7 had a significantly lower median survival time (4 vs 15 months).³⁹ Hatano and colleagues⁴⁰ evaluated the role of preoperative PET in predicting the prognosis of patients after resection. In patients with SUV ratio of more than 2, the overall survival was significantly shorter than in those with a lower SUV ratio (182 vs 2310 days). Seo and coworkers⁴¹ had similar results, concluding that the overall survival and disease-free survival were significantly lower in the high SUV ratio group (>2) compared with the low SUV ratio group.

HCC is one of the major indications for liver transplantation; however, appropriate patient selection can be difficult. A study of 43 patients with HCC who underwent PET before liver transplantation found that patients with advanced PET-negative tumors and patients with HCC meeting the Milan criteria had a comparable 3-year survival rate (80% vs 94%).⁴² The HCC recurrence rate in this study was 50% in the PET-positive group compared with 3.8% in the PET-negative group. Another study by Lee and colleagues⁴³ attempted to evaluate FDG PET as a prognostic factor in predicting HCC recurrence after liver transplantation. They found that the ratio of tumor SUV_{max} to normal liver SUV_{max} was the most significant parameter for the

prediction of tumor recurrence, with a cutoff value of 1.15. Among the tumor recurrence patients, 93% had a value of 1.15 or more, whereas just 18% of the nonrecurrence patients had a value of 1.15 or more. The 1- and 2-year recurrence-free survival rates were significantly different between the two groups.

Patients with HCCs that are nonresectable or those awaiting transplantation can be treated with ablation or embolization. PET has been shown to play a role in monitoring response to such treatments. Torizuka and coworkers⁴⁴ found that after transarterial chemoembolization, increased or similar FDG uptake relative to normal liver was suggestive of residual viable tumor, whereas decreased or absent FDG uptake indicated more than 90% necrosis. Paudyal and coworkers⁴⁵ found that after radiofrequency ablation, PET detected recurrence earlier than CT and had a higher overall detection rate (92% for PET vs 75% for CT). Han and colleagues⁴⁶ found that PET/CT was valuable in patients who had unexplained serum α -fetoprotein elevation after either transarterial chemoembolization or radiofrequency ablation and a normal multiphasic CT scan.

For patients with advanced-stage HCC or with disease progression after locoregional therapy, treatment options are limited. However, studies have recently demonstrated survival benefit with sorafenib for patients with advanced HCC. PET/CT may have a role in monitoring of patients treated with sorafenib and for predicting response to treatment. A report of two patients with positive FDG PET at baseline found that a PET scan early after the start of treatment seemed to be a promising technique for monitoring early response.⁴⁷ A more recent study by Lee and colleagues⁴⁸ concluded that the degree of FDG uptake on baseline PET scan significantly correlated with overall survival and progression-free survival for such patients receiving sorafenib treatment.

METASTASES

Metastatic disease accounts for the majority of malignant hepatic lesions. The presence of liver metastases often guides the management of patients and is one of the main determinants of survival. FDG PET has been shown to be highly sensitive in detecting liver metastases (Fig. 68-3). Delbeke and coworkers³³ found that FDG PET detected all liver metastases larger than 1 cm from a number of different primary tumors. A meta-analysis by Kinkel and associates⁴⁹ found that at equivalent specificity, FDG PET was the most sensitive noninvasive imaging modality for the diagnosis of hepatic metastases from cancers of the gastrointestinal tract. Another meta-analysis by Bipat and colleagues⁵⁰ concluded that FDG PET had

Figure 68-3 Liver metastasis.

A. Contrast-enhanced CT demonstrates an ill-defined area of low attenuation adjacent to the falciform ligament (arrow), which was previously attributed to focal fat. **B.** However, PET/CT demonstrates increased FDG avidity (arrow), consistent with a metastasis in this patient with a history of colon cancer.

significantly higher sensitivity on a per-patient basis compared with CT and MRI, but not on a per-lesion basis, in patients with colorectal liver metastases.

Hepatic resection is the most effective therapy for a subset of patients with liver metastases; however, strict selection criteria are paramount as there is no survival benefit if residual disease remains after hepatectomy. Arulampalam and colleagues⁵¹ found that preoperative FDG PET in patients with colorectal liver metastases altered management in 39% of patients, with avoidance of unnecessary surgery being the most common change. A study by Fernandez and colleagues⁵² found that use of FDG PET to assess patients with colorectal liver metastases being considered for partial hepatectomy was associated with excellent postresection 5-year survival.

Complete surgical resection is the best chance of cure in patients with liver metastases. However, in some patients, this is not feasible because of location of the tumor, multifocality, or insufficient functional liver reserve. In these cases, local ablative techniques may have a role to play. PET may have a role in follow-up of patients who underwent ablation (Fig. 68-4). Donckier and coworkers⁵³ compared PET and CT in 28 metastatic tumors 1 week, 1 month, and 3 months after radiofrequency ablation. The PET scan performed at 1 week found residual disease in 4 cases that was not identified on any of the CT scans at 1 week, 1 month, and 3 months.

Radioembolization with ⁹⁰Y microspheres has emerged as a palliative treatment for hepatic metastases of various tumors.

Szyszkowski and colleagues⁵⁴ performed a study evaluating the role of PET compared with Response Evaluation Criteria in Solid Tumors (RECIST) in early response assessment after ⁹⁰Y radioembolization in 21 patients. They found that 86% of patients demonstrated decreased PET activity at 6 weeks, whereas only 13% showed a partial response in the size of tumor on CT scan. A study by Haug and coworkers⁵⁵ in 58 patients with breast cancer metastases treated with ⁹⁰Y radioembolization found that PET/CT performed 3 months after treatment was the strongest predictor of survival (67 weeks in responders vs 43 weeks in nonresponders). Furthermore, they found that a pretreatment SUV_{max} of more than 20 was associated with a significantly shorter median survival than was SUV_{max} of 20 or less (21 vs 52 weeks). Another study comparing FDG PET/CT with RECIST and tumor density criteria found that PET/CT significantly predicted progression-free survival (the median progression-free survival in patients with a partial response was 12 months compared with 5 months in those with stable disease), whereas RECIST and tumor density criteria did not.⁵⁶

During the last few years, the addition of biologic agents (anti-epidermal growth factor receptor antibodies and anti-vascular endothelial growth factor antibodies) to conventional chemotherapy has increased overall survival in patients with metastatic colorectal cancer; it also has improved response rates and can render unresectable liver metastases resectable. A report by Bertolini and coworkers⁵⁷ found that patients with nonoptimally resectable colorectal metastases treated with FOLFOX

Figure 68-4 Recurrent hepatic tumor. Contrast-enhanced CT demonstrates an ill-defined low-attenuation lesion in the periphery of the liver (**A**, arrow), which demonstrated increased FDG avidity on PET (**B**, arrow). Biopsy confirmed a metastasis from colon cancer, which was treated with radiofrequency ablation. Contrast-enhanced CT 1 month after ablation demonstrated a nonenhancing low-attenuation ablation zone (**C**, arrow), which is photopenic on PET (**D**, arrow), consistent with treatment response. Contrast-enhanced CT 9 months after ablation demonstrates a low-attenuation area adjacent to the ablation zone (**E**, arrow), which demonstrated increased FDG avidity (**F**, arrow). Findings are consistent with local recurrence.

(folinic acid, fluorouracil, oxaliplatin) and bevacizumab who achieved at least 1 unit reduction in SUV_{max} had longer progression-free survival (median progression-free survival of 22 vs 14 months). Another study found that low follow-up SUV_{max} and complete metabolic response were favorable prognostic factors in patients with metastatic colorectal cancer who underwent liver surgery with curative intent after neoadjuvant chemotherapy with bevacizumab.⁵⁸

LYMPHOMA

Primary hepatic lymphoma is defined as a lesion or lesions confined to the liver only without the involvement of any other organ or lymph nodes; it is extremely rare, representing less than 1% of all extranodal lymphomas. It usually is manifested as a solitary mass (Fig. 68-5) or as multiple discrete masses.⁵⁹ Rarely, the disease is manifested as diffuse involvement of the liver.⁶⁰ Case reports have found the lesions to be hypermetabolic on PET/CT.^{61,62}

PITFALLS

Causes of false-negative FDG PET findings include small size of lesion, underestimation of uptake, misregistration of foci, and recent completion of chemotherapy. Underestimation of FDG uptake and misregistration of foci are caused by the physiologic motion of the liver during emission scans. False-positive findings for malignant changes on PET have also been reported. Causes include intrahepatic abscess and benign inflammatory lesions, such as regenerative nodules in a cirrhotic liver.

Spleen

There is usually slightly less FDG uptake in the normal spleen than in the liver.

LYMPHOMA

Splenic involvement in lymphoma can be primary or secondary; secondary splenic lymphoma is much more common. The spleen is involved in one third of all Hodgkin's lymphoma and 30% to 40% of non-Hodgkin's lymphoma at presentation. Primary splenic lymphoma is defined as lymphomatous involvement of the spleen with or without splenic hilar lymphadenopathy and is rare, accounting for 1% to 2% of all lymphomas at presentation.⁶³ The two patterns of splenic lymphomatous infiltration on FDG PET/CT are a diffusely FDG-avid spleen,

with more FDG activity than in liver and normal bone marrow and often with a normal CT appearance (Fig. 68-6), and solitary or multiple FDG-avid splenic lesions.⁶⁴ A study has found the sensitivity and specificity of CT, PET, and PET/CT for identification of splenic involvement at initial staging in lymphoma to be 91% and 96%, 75% and 99%, and 100% and 95%, respectively.⁶⁵

Primary nonhematopoietic tumors of the spleen are extremely rare. They may arise from the sinus epithelium (angiosarcoma and hemangioendotheliomas) or from connective tissue (spindle cell sarcoma and fibrosarcoma).

METASTASES

Splenic metastases are encountered in 2.3% to 12.9% of post-mortem examinations in cancer patients; melanoma and lung, breast, and ovarian cancer are the most common malignant neoplasms to metastasize to the spleen (Fig. 68-7). Metser and associates⁶⁶ found that the sensitivity, specificity, positive predictive value, and negative predictive value of FDG PET/CT in differentiating benign from malignant solid splenic lesions in patients with and without malignant disease were 100%, 100%, 100%, and 100% versus 100%, 83%, 80%, and 100%, respectively. They also concluded that in patients with known malignant disease, an SUV threshold of 2.3 correctly differentiated benign from malignant lesions with sensitivity, specificity, positive predictive value, and negative predictive value of 100%, 100%, 100%, and 100%, respectively. They also found that in patients without known malignant disease, false-positive results were due to granulomatous disease.

PITFALLS

Increased splenic activity can be seen in the post-therapy period, especially after hematopoietic stimulants, and can limit the evaluation of splenic involvement by lymphoma or can result in a false-positive finding. However, associated diffuse symmetric FDG uptake in bone marrow of the axial skeleton can suggest hematopoietic stimulation instead of true splenic lymphomatous involvement.⁶³

Most benign solid splenic lesions, such as hamartomas and hemangiomas of the spleen, are not expected to demonstrate abnormal FDG uptake. However, some benign lesions exhibit abnormal uptake of FDG, most commonly splenic abscess and active granulomatous disease involving the spleen. Conversely, non-FDG-avid tumors, such as some renal and thyroid cancers, may metastasize to the spleen. Therefore,

Figure 68-5 Hepatic lymphoma. **A.** Contrast-enhanced CT demonstrates a solitary, large, low-attenuation lesion in the liver (arrow) adjacent to the gallbladder. **B.** PET/CT demonstrates the increased FDG avidity of the lesion. Percutaneous biopsy confirmed lymphoma.

Figure 68-6 Splenic lymphoma. **A.** PET scan demonstrated abnormal increased FDG avidity in the spleen compared with the liver, consistent with lymphoma. **B.** PET scan 1 month after chemotherapy demonstrates resolution of increased FDG avidity consistent with treatment response.

Figure 68-7 Splenic metastasis. **A.** Contrast-enhanced CT demonstrates a low-attenuation mass in the spleen (arrow). **B.** This splenic mass demonstrates increased FDG avidity on PET/CT. Findings are consistent with a splenic metastasis in a patient with known colon carcinoma. The apparent focal area of FDG uptake in the periphery of the liver (arrow) without a CT correlate is due to misregistration from excreted FDG in the right renal collecting system.

when a non-FDG-avid splenic lesion is encountered, the CT portion of the PET/CT study should be assessed for potential non-FDG-avid malignant lesions.⁶⁷

Pancreas

Minimal physiologic uptake is identified in the pancreas on PET/CT. The average SUV_{max} for normal pancreas is calculated as 2.7 ± 1.3 (range, 1.8-5.1).⁶⁸

PANCREATIC ADENOCARCINOMA

The role of imaging in patients with suspected pancreatic cancer is to depict lesions and to determine whether tumors are resectable. Pancreatic adenocarcinoma usually is manifested as an area of increased uptake (Fig. 68-8); however, it may demonstrate a low level of FDG uptake or no uptake based on the degree of desmoplastic response and tumor biology.⁶⁹ Irrespective of size, the SUV_{max} is typically higher in malignant lesions,

Figure 68-8 Pancreatic adenocarcinoma. **A.** Contrast-enhanced CT demonstrates a 2-cm mass in the head of the pancreas (arrow) with a stent in the adjacent common bile duct. **B.** PET demonstrates increased FDG avidity in the mass (arrow). Endoscopic biopsy confirmed pancreatic adenocarcinoma.

and therefore FDG PET may be useful in depicting small pancreatic lesions (<2 cm) and those that are isoattenuating to adjacent normal pancreatic parenchyma, which are difficult to detect at CT. Okano and associates⁷⁰ reported sensitivities of 100% for FDG PET and 40% for contrast-enhanced CT for depicting lesions smaller than 2 cm. Delbeke and coworkers⁷¹ demonstrated that FDG PET had a higher sensitivity, specificity, and accuracy than CT in diagnosis of pancreatic carcinoma (92%, 85%, and 91% for FDG/PET vs 65%, 61%, and 65% for CT, respectively). In another study, Lemke and colleagues⁷² compared the diagnostic value of CT, PET, and PET/CT fusion in 104 patients with pancreatic cancer and reported that the image fusion improved the sensitivity of detection of malignant disease from 77% (CT) and 84% (PET) to 89% (image fusion). Kauhanen and associates⁷³ found that diagnostic accuracy of FDG PET/CT for pancreatic malignant disease was 89% compared with 76% and 79% for multidetector CT and magnetic resonance imaging, respectively. Buchs and colleagues⁷⁴ concluded that enhanced PET/CT seemed to be superior to unenhanced PET/CT in the detection of pancreatic cancer, with the sensitivity of enhanced PET/CT being 96% compared with 72% for unenhanced PET/CT and the specificity being 67% versus 33%.

To determine the resectability of the tumor, it is crucial that the presence or absence of metastasis be determined and that the degree of venous (superior mesenteric vein and portal vein) involvement and relationship to adjacent arteries (superior mesenteric artery, celiac axis, hepatic artery, gastroduodenal artery) be evaluated.⁷⁵ Strobel and coworkers⁷⁶ concluded that contrast-enhanced PET/CT was significantly superior to PET alone for the preoperative assessment of cancer resectability, and there was a trend for enhanced PET/CT to be superior to unenhanced PET/CT. PET and unenhanced PET/CT both had sensitivities of 100%, but PET alone had specificity of 44%, whereas unenhanced PET/CT had 56% specificity. Contrast-enhanced PET/CT was superior to unenhanced PET/CT with a sensitivity of 96% and a specificity of 82%. Regarding the presence of nodal metastases (N stage), FDG PET/CT has been found to have a sensitivity of 30% to 42%, whereas sensitivity for distant metastases (M stage) has been found to be 88% to 94%.^{73,77}

FDG PET/CT may also have a role in planning the radiation field in patients with pancreatic cancer. A study by Topkan and

coworkers⁷⁸ in 14 patients undergoing radiation planning for unresectable pancreatic cancer found that the addition of PET resulted in an average 30% increase in gross tumor volume in 5 patients. Another role for FDG PET/CT is in predicting pathologic response to preoperative chemoradiation therapy (CRT). Kittaka and associates⁷⁹ found that a better pathologic response can be expected in pancreatic cancer patients who have a high pre-CRT SUV (≥ 4.7) and a high regression index (≥ 0.46), determined by $1 - \text{post-CRT SUV/pre-CRT SUV}$.

FDG PET/CT has also been shown to have a role in the diagnosis of recurrent pancreatic cancer. Sperti and coworkers⁸⁰ found that tumor relapse after pancreatic cancer resection was detected by CT in 35 patients and by PET in 61 of 63 patients with recurrence and that PET results influenced treatment strategies in 44% of patients. Casneuf and associates⁸¹ concluded that in assessing for recurrence, the sensitivity (90%) and accuracy rate (92%) were highest for PET and PET/CT, whereas CT yielded a lower sensitivity (80%). A study by Ruf and colleagues⁸² demonstrated that 96% of local recurrences were detected by PET compared with 39% by CT or MRI. Asagi and colleagues⁷⁷ found that enhanced PET/CT correctly detected local recurrence in all of the 11 cases of recurrence, whereas enhanced CT detected only 7 of 11 cases.

CYSTIC NEOPLASMS

Cystic neoplasms of the pancreas encompass a wide range of pathologic conditions from benign lesions to malignant, potentially malignant, and borderline tumors. Sperti and coworkers⁸³ found that FDG-avid intraductal papillary mucinous neoplasms are frankly malignant or invasive, and conversely, FDG-negative lesions may be benign, borderline malignant, or noninvasive malignant. Other studies have found that by use of a cutoff SUV of 2.5, it was feasible to differentiate between benign and malignant intraductal papillary mucinous neoplasms.⁸⁴⁻⁸⁶

PITFALLS

Serum glucose levels can affect FDG PET findings. One study found that FDG PET has better sensitivity (86%) for pancreatic tumor depiction in patients who are euglycemic than in those with elevated glucose levels (42%).⁸⁷ False-positive results can

be due to inflammation or infection (Fig. 68-9), inflammatory pseudotumor, pancreatic tuberculosis, chronic pancreatitis, and focal high-grade dysplasia.⁸⁸

Adrenal Glands

Adrenal incidentalomas are found in approximately 4% to 10% of all CT examinations in the general population⁸⁹; 80% of incidentally found adrenal masses in healthy individuals and 40% to 57% of adrenal incidentalomas in those with a known primary malignant neoplasm are benign.⁹⁰ The normal adrenal gland is usually barely visible on FDG PET, and normal mild FDG uptake in the location of the glands can be visible on the coregistered CT scan of a combined PET/CT scan. The maximum SUVs of normal adrenal glands range from 0.95 to 2.46.⁹¹

METASTASES

An adrenal lesion is usually considered malignant if its intensity is higher than that of liver; however, because the average mean SUV of the liver is 1.5 to 2.0, physiologic adrenal uptake may be in the range of malignant lesions in some cases. Jana and colleagues⁹² reported 93% sensitivity and 96% specificity with

use of lesion activity higher than liver uptake as a criterion for malignancy (Fig. 68-10). Metser and coworkers⁹³ found that when 3.1 was used as a cutoff for SUV_{max} PET/CT had a sensitivity and specificity of 98.5% and 92% in the differentiation of malignant from benign lesions. Watanabe and coworkers⁹⁴ concluded that the adrenal-to-liver SUV ratio is the best parameter for differentiation of adrenal metastases from adenomas; use of an adrenal-to-liver SUV ratio cutoff value of 1.37 yielded a sensitivity of 96% and specificity of 100%. A meta-analysis by Boland and colleagues⁹⁵ found that FDG PET had 97% sensitivity and 91% specificity in the differentiation between malignant and benign adrenal disease.

ADRENOCORTICAL CARCINOMA

Adrenocortical carcinoma is the most common primary malignant neoplasm of the adrenal cortex but still accounts for less than 5% of all adrenal incidentalomas. Groussin and coworkers⁹⁶ found that with use of a cutoff value above 1.45 for adrenal-to-liver SUV_{max} ratio, the sensitivity and specificity to distinguish adrenal adenoma from adrenocortical carcinoma were, respectively, 100% and 88%. Becherer and colleagues⁹⁷ evaluated FDG PET in patients with known adrenocortical carcinoma and reported that FDG PET had a sensitivity and specificity of 100%

Figure 68-9 Infection simulating recurrent pancreatic adenocarcinoma. **A.** PET/CT in a patient 9 months after a Whipple procedure for ampullary carcinoma demonstrates soft tissue with increased FDG avidity surrounding the superior mesenteric vessels (arrow). Focal uptake in the renal parenchyma bilaterally is secondary to misregistration of excreted isotope in the renal collecting system bilaterally. Note is also made of increased FDG uptake in the duodenum (arrowhead). Percutaneous biopsy found actinomycosis. Infection is one of the causes of pancreatic FDG PET/CT false-positive findings. **B.** PET/CT after treatment with intravenous penicillin demonstrates resolution of FDG avidity.

Figure 68-10 Adrenal metastasis from lung cancer. **A.** Contrast-enhanced CT demonstrates a 2.9-cm left adrenal nodule (arrow) that is incompletely characterized. **B.** PET/CT demonstrates increased FDG avidity in the nodule. Percutaneous biopsy was positive for adenocarcinoma from a lung primary.

Figure 68-11 Adrenal lymphoma. **A.** Contrast-enhanced CT demonstrates essentially normal-appearing bilateral adrenal glands. **B.** PET scan demonstrates increased FDG avidity in the glands bilaterally (arrow indicating right uptake). Percutaneous biopsy of the left adrenal gland confirmed lymphoma.

Figure 68-12 Adrenal adenoma. **A.** Contrast-enhanced CT demonstrating a 2.2-cm left adrenal nodule (arrow) that is incompletely characterized. **B.** Left adrenal nodule demonstrates increased FDG avidity, greater than that of the liver, on PET/CT. On resection, this was shown to be an adenoma; 5% of adrenal adenomas may show increased FDG uptake falsely positive for malignancy as was evident in this case.

and 95%, respectively. The addition of PET detected additional lesions compared with anatomic imaging in 30% of patients and modified treatment in 20%. Patients with initial complete surgery have a high risk of relapse within the first 2 years of follow-up. One study found that 38% of patients with local relapses were detected with PET/CT and not with CT, which led to change in treatment in three of these five patients.⁹⁸ They also found that the intensity of FDG uptake (SUV_{max}) and the FDG uptake volume were significantly associated with survival.⁹⁸

PHEOCHROMOCYTOMA

Pheochromocytomas are relatively rare catecholamine-secreting neuroendocrine tumors that arise from the chromaffin cells of the adrenal medulla. Shulkin and coworkers⁹⁹ compared FDG PET with metaiodobenzylguanidine (MIBG) scintigraphy for the detection of pheochromocytomas. They found that for benign pheochromocytomas, MIBG scintigraphy had a sensitivity of 83%, whereas FDG PET had a sensitivity of 58%. However, for malignant pheochromocytomas, MIBG scintigraphy had a sensitivity of 88% and FDG PET had a sensitivity of 82%. Although MIBG scintigraphy had a better sensitivity than FDG PET, all of the MIBG-negative lesions showed avid FDG uptake. A more recent, large prospective study in patients with pheochromocytomas and paragangliomas found that primary tumors are equally well identified by FDG PET/CT and ¹²³I-MIBG single photon emission computed tomography (SPECT), currently the standard imaging modality. The investigators also found that metastases are better detected by FDG

PET than by ¹²³I-MIBG SPECT, with sensitivities of 80% and 49%, respectively.¹⁰⁰

LYMPHOMA

Primary adrenal lymphomas are rare and typically bilateral, homogeneous, and infiltrating, with the enlarged adrenal glands tending to maintain their overall shape (Fig. 68-11). Secondary adrenal involvement has been reported in 1% to 4% of affected patients. PET/CT has been found to be valuable in distinguishing nonfunctioning adrenal neoplasms or hyperplasia from lymphomatous involvement.⁹⁰

PITFALLS

Both false-positive and false-negative adrenal FDG PET findings have been reported. Causes of false-positive results include significant FDG uptake in some adrenal adenomas (Fig. 68-12), adrenal endothelial cysts, and inflammatory and infectious lesions. Increased FDG uptake in the suprarenal or retrocrural region due to brown fat may mimic an adrenal lesion and is another pitfall of PET; however, such patients should be readily recognized as they have the characteristic brown fat pattern of FDG uptake in the neck and mediastinum. Adrenal metastatic lesions with hemorrhage or necrosis, small metastatic lesions, and metastases from non-FDG-avid primary tumors, such as pulmonary bronchoalveolar carcinoma and carcinoid tumors, may be causes of false-negative PET adrenal findings.¹⁰¹

Gallbladder
Spleen
Lymph Nodes
Peritoneum
Gastrointestinal Tract

Future Directions

Summary

Diffusion-weighted magnetic resonance imaging (MRI) was introduced into clinical practice in the mid-1990s, primarily in brain imaging because of its exquisite sensitivity to detect ischemic infarcts. In the past decade, technical advancements have allowed the technique to be translated to body imaging, and abdominal diffusion-weighted imaging (DWI) is now well established. The clinical applications of abdominal DWI are both oncologic and nononcologic; the oncologic applications have been especially helpful.

DWI provides a contrast mechanism for the qualitative and quantitative assessment of tissues. The technique is complementary to and in some situations a viable alternative to gadolinium-enhanced MRI. Abdominal DWI does not require contrast media to be administered, yet it frequently highlights pathologic processes visible on contrast-enhanced techniques with increased conspicuity. The technique allows disease detection and assessment beyond that achievable by morphologic imaging alone.

This chapter discusses the principles of DWI, technical implementation, image interpretation, clinical applications,

and potential pitfalls of the technique as applied to imaging of the abdomen.

Principles of Diffusion-Weighted Imaging

At its most fundamental level, DWI uses an imaging sequence that probes the microscopic mobility of water. The true diffusion coefficient of water is a measure of the effective displacement of water molecules per unit time, which is a random process (brownian motion) and is temperature dependent. Conceptually, it may be useful to consider the diffusion coefficient as a reflection of the freedom of movement of water molecules in a particular volume.

Several biophysical mechanisms can alter the random brownian motion of water molecules in tissues. These include cellular density, cell membrane integrity, cellular structural organization, and the presence of macromolecules that bind to water.¹ The term *apparent diffusion coefficient* (ADC) represents the observed diffusion constant as the water molecules in tissues are modified by these biophysical interactions.

The image contrast on diffusion-weighted images is based on the differences in the diffusivity of water molecules. For example, tumor tissues exhibit low water diffusivity (or “impeded diffusion”) because of the relatively high density of cellular membranes. This increases the frequency of water proton–cell membrane interactions, which thus impedes water mobility. By contrast, a simple cyst containing water only would show high diffusivity as there are no barriers to water diffusion (Fig. 69-1).

OBSERVING AND MEASURING WATER DIFFUSION WITH MAGNETIC RESONANCE IMAGING

The quantification of diffusion with MRI on current clinical systems is based on experiments by Stejskal and Tanner in the 1960s.² The introduction of a pair of symmetric gradients before and after the 180-degree refocusing pulse of a conventional T2-weighted spin-echo sequence “sensitizes” the sequence to water motion (Fig. 69-2). Static water spins dephased by the first gradient lobe would experience a complete rephasing by the second gradient lobe, thereby maintaining their signal. However, moving water spins will be in a different position at the time of the second lobe and thus not be rephased by the same degree, resulting in signal attenuation. Thus the presence of water diffusion is observed as signal loss on DWI. The greater the displacement of water molecules (i.e., the higher their diffusivity), the greater will be the degree of signal attenuation.

Figure 69-1 Diffusion of water molecules within schematized voxels of interest. **A.** Free diffusion. Water molecules (small blue circles) have relatively unimpeded motion in a hypocellular environment, with the majority of the molecules diffusing freely within the extracellular space. The voxel would return a high apparent diffusion coefficient. **B.** Restricted diffusion. In a hypercellular environment, such as within viable tumor, water molecules encounter frequent collisions with cell membranes. This impedes the free movement of water molecules, which is quantified as a low apparent diffusion coefficient within the voxel.

Figure 69-2 Stejskal-Tanner diffusion-weighted spin-echo MR pulse sequence diagram. The time line for the phase-encoding gradient is omitted to simplify the diagram. Two symmetric diffusion-sensitizing gradients (red) are inserted before and after the 180-degree radiofrequency (RF) refocusing pulse. The diffusion sensitivity or b value of the sequence is determined by G, amplitude; δ , duration of the sensitizing gradient; and Δ , time between the two sensitizing gradient lobes. EPI, Echo planar imaging.

As with any MR sequence, the image contrast on DWI results from a combination of different tissue magnetic properties. In DWI, as this is significantly affected by water diffusion, the term *diffusion weighted* is used. However, the image contrast is influenced by both the underlying sequence (usually a T2-weighted sequence with a relatively long repetition time) and the strength of the diffusion weighting, which is given by the b value (diffusion weighting factor). The b value on a clinical scanner is usually altered by changing the amplitude of the diffusion sensitizing gradient, although it may be possible to vary the gradient duration and time interval between the paired gradients.

A b factor of zero ($b = 0 \text{ s/mm}^2$) indicates no diffusion weighting, and the image is analogous to a T2-weighted image. In the abdomen, lower b values applied often range from 50 to 150 s/mm^2 ; higher b values typically range between 500 and 1000 s/mm^2 . DWI in the abdomen is usually performed with use of at least two b values, a lower and a higher b value. To calculate the quantitative ADC value, the relative signals of each voxel at different b value are mathematically fitted by an exponential function according to the following equation:

$$\text{ADC} = \ln(S_1/S_0)/(b_1 - b_0)$$

where S_0 is the signal intensity with the b value of 0 and S_1 is the signal intensity with b value = b (this equation assumes the repetition time and echo time are held constant). A graphic representation of this formula is shown in Figure 69-3A.

INTRAVOXEL INCOHERENT MOTION MODEL

In certain organs such as the liver, the measured signal declines sharply with increasing diffusion weighting over the lower range of b values (typically $0\text{--}100 \text{ s/mm}^2$); the signal then attenuates more gradually with further increase in the b values. This biexponential behavior of signal attenuation is attributed to intravoxel incoherent motion (IVIM),³ in which intravascular microcapillary perfusion generates a pseudodiffusion effect at low b values. Thus, in calculating ADC values, the inclusion of these low b values can result in overestimation of tissue diffusivity. At higher b values, the pseudodiffusion effect is largely negated, and estimation of tissue diffusivity in tissues with significant tissue perfusion may be more reliable if the lower b values are excluded. However, the more sophisticated approach is to apply the biexponential IVIM model to the data fitting, from which the pseudodiffusion coefficient (D^*), perfusion fraction (f), and tissue diffusion coefficient (D) are derived (Fig. 69-4). Both D^* and f reflect tissue perfusion and can vary independently.

The contribution of microcapillary perfusion may be considered in quantitative DWI analysis and is more significant in certain organs and pathologic processes. However, the utility of IVIM-based quantitative metrics is still largely confined to research,⁴ as accurate estimation of the perfusion-sensitive parameters can be challenging, particularly in lesions with inherently low vascular perfusion. Furthermore, there is currently a lack of commercial software for data analysis. Nonetheless, emerging observations suggest that in well-conducted studies with sufficient image signal-to-noise ratio (SNR) and in diseases or organs with significant perfusion effects, IVIM analysis may provide additional information to aid disease characterization.

Technical Considerations

IMAGE ACQUISITION AND SEQUENCE OPTIMIZATION

DWI sequences for clinical imaging of the abdomen are available on most current 1.5T and 3.0T MRI scanners. As in any MR sequence, tradeoffs between image spatial resolution, image SNR, and scan duration are often made, depending on the clinical indication. The technique that is most widely applied is single-shot fat-suppressed spin-echo echo planar imaging

Figure 69-3 **A.** Graph schematic of measured signal intensities (in logarithmic scale) over the range of b values illustrating the concept of apparent diffusion coefficient (ADC). The ADC value represents the slope of the line that describes this relationship within each voxel. A voxel within a cyst would show greater signal attenuation with each incremental increase in the b value, resulting in a high measured ADC (steeper slope). The signal attenuates less sharply as the b value increases within voxels containing a tumor microenvironment, which corresponds to a lower ADC (more gentle slope). **B.** Series of diffusion-weighted images of the liver showing the marked signal attenuation of a cyst (arrow) as the b value increases. The tumor deposits (arrowheads) show more gradual signal attenuation and are conspicuous on the b800 image because of a relatively higher lesion-to-background contrast. Derived ADC map shows the higher ADC of the cyst represented by high signal intensity, compared with the lower ADC of the tumor represented by low signal intensity.

(SS-EPI). The primary merit of this technique is the speed of acquisition (with subsecond acquisitions of the entire k -space), but the sequence is prone to low SNR as well as ghosting, image distortion, blurring, and susceptibility artifacts.⁵ Other k -space acquisition techniques, such as multishot EPI DWI, turbo spin-echo DWI, and radial schemes of k -space acquisition (PROPELLAR DWI), may have potential to reduce some of the artifacts associated with the SS-EPI technique but are not widely implemented.

The underlying principles that guide imaging parameter selection in SS-EPI should be optimized for good SNR and reduction of artifacts. It is beyond the scope of this chapter to discuss the broader MR principles that affect image SNR and artifacts, but a few points that are particularly relevant to EPI DWI are mentioned here. First, fat suppression is routinely used to reduce the large chemical shifts in EPI and to increase the dynamic range of DWI images. This can be achieved either by inversion recovery (e.g., short tau inversion recovery) technique, which gives more uniform fat suppression but less SNR, or with chemical fat-selective saturation (e.g., spectral selected attenuation with inversion recovery or chemical shift selective imaging), which yields better SNR but is more susceptible to magnetic field inhomogeneities. Second, the echo time should be minimized as this increases the SNR; the repetition time should be sufficiently long to avoid T1 saturation effects (at least three to five times that of the T1 relaxation time of the imaged tissue). Use of a simultaneous gradient scheme (e.g., tetrahedral encoding or three-scan trace) allows the echo time to be reduced. Third, the number of signal averages can be increased to achieve better SNR, although at a cost of increased scan time. Some scanners allow the

number of averages performed to vary with the b value, with more averages performed for SNR-poor high- b value DWI images. Last, parallel imaging should always be applied for body DWI as it shortens the echo train lengths, thereby reducing susceptibility and field inhomogeneity-related artifacts as well as reducing the acquisition time (Tables 69-1 and 69-2). The reader is referred to the review article by Koh and associates⁶ for a more detailed discussion of the technical parameters that influence the imaging quality of EPI DWI images.

COMPENSATION FOR PHYSIOLOGIC MOTION

Unlike in the brain, which is a reasonably static organ, several physiologic processes create motion-related phase artifacts in the abdomen that degrade image quality. This includes coherent movement, such as respiratory motion and bowel peristalsis, and noncoherent motion, such as cardiac pulsation.

Strategies to overcome artifacts arising from respiratory motion include breath-hold DWI, respiratory or navigator triggered/controlled DWI, and free-breathing DWI with multiple signal averages. Of these three techniques, breath-hold SS-EPI DWI of the abdomen is the fastest to perform, with coverage of the entire liver or abdomen over two breath-holds, each lasting approximately 20 seconds. The images retain good anatomic detail and are not degraded by respiratory averaging. However the major drawback is the lower SNR of the source data, which imposes limits on the acceptable spatial resolution (typically wider section thicknesses of 8 to 10 mm) and the maximum b value used (as higher b factors decrease the SNR). Fewer b values are obtained with this technique because of the limited number of b -value acquisitions that can be

Figure 69-4 Graph schematic shows calculation of diffusion parameters by intravoxel incoherent motion (IVIM) analysis. Plot shows the logarithm of the signal intensity for each image voxel acquired at the same anatomic position across the range of b values applied. A biexponential behavior of signal attenuation is observed because of the different predominant processes at low and high b values causing signal attenuation. D* represents the slope at the range of low b values (typically 0-100 s/mm²). The more rapid loss of signal (steeper slope) at lower b values is attributed to the dominant effect of microcirculatory perfusion, producing a pseudodiffusion effect. D represents the slope at the range of high b values (more than 100 s/mm²). The more gradual decline in signal at this portion of the curve reflects true diffusivity effects. Note that a higher concentration of data points is acquired in the lower range of b values to improve the accuracy of the calculation of D*. (Modified from Koh DM, Collins DJ, Orton MR: Intravoxel incoherent motion in body diffusion-weighted MRI: Reality and challenges. *AJR Am J Roentgenol* 196:1351-1361, 2011.)

accommodated within a breath-hold. Breath-holding techniques may also be more sensitive to susceptibility and pulsation artifacts.¹

Respiratory or navigator triggered/controlled techniques synchronize data acquisition with respiratory movement, and data are acquired only within a certain period of the respiratory cycle (usually the expiratory phase). The advantages of this method include better subjective image quality, higher SNR, higher lesion-to-liver contrast ratio, and more precise ADC quantification compared with breath-hold DWI.^{7,8} However acquisition times are increased substantially (up to 5 to 6 minutes), and ADC measurements may be less reproducible compared with breath-hold and free-breathing DWI.⁹ In addition, the technique may result in pseudo-anisotropy artifacts related to the gated image acquisition.¹⁰

In free-breathing EPI DWI, signal averaging from multiple acquisitions of the same imaging volume produces images with high SNR. Thin slice partitions (4-5 mm) are possible, and this allows multiplanar reconstructions of reasonable quality. A larger number of b values can be accommodated, which enables evaluation of ADC as well as IVIM parameters of lesions. However, image acquisition time is longer compared with

TABLE 69-1 List of Recommended Optimizations of Echo Planar Diffusion-Weighted Imaging	
Problem	Solution
Poor signal-to-noise ratio	Use shortest echo time available Echo time can be reduced with the following techniques : Parallel imaging (maximum 2x) Simultaneous gradient application scheme (e.g., three-scan trace) Increase of receiver bandwidth Use of monopolar gradient scheme Use multiple averages (maximum 6) Choose larger voxel size (increase field of view, smaller matrix, increase section thickness) Choose lower b values Image at higher field (3T) Optimize receiver bandwidth
Poor fat suppression and chemical shift artifact	Use nonchemical selective fat suppression scheme (e.g., short tau inversion recovery) Increase receiver bandwidth Use combination fat suppression schemes at 3T
Eddy current artifacts (geometric distortion, image shearing)	Optimize/increase receiver bandwidth Use of bipolar gradient scheme Use of parallel imaging Simultaneous gradient application scheme
Nyquist (N/2) ghosting	Decrease receiver bandwidth

TABLE 69-2 Typical Scan Parameters Used to Perform Abdominal Diffusion-Weighted Magnetic Resonance Imaging	
Parameter	Value
Pulse sequence	Single-shot spin-echo echo planar imaging
Imaging plane	Axial
Field of view, mm	380 × 380
Matrix size	150 × 256
Repetition time (TR), ms	14,000
Echo time (TE), ms	72
Echo planar imaging factor	150
Parallel imaging factor	2
Number of signals averaged	4
Section thickness, mm	5
Direction of motion-probing gradients	3-scan trace
Receiver bandwidth	1800 Hz/pixel
Fat suppression	Short tau inversion recovery (inversion time, 180 ms)
b value, s/mm ²	0, 100, 900
Breathing technique	Free breathing
Acquisition time	4 minutes 30 seconds

breath-hold imaging (in the region of 3 to 6 minutes to cover the liver), and signal/volume averaging may result in suboptimal characterization of lesion heterogeneity, especially for smaller lesions. Even allowing for the presence of motion, ADC measurements in free-breathing DWI have been shown to be robust and comparable or even superior to breath-hold DWI.⁹

Cardiac pulsation results in spin dephasing, which is most prominent in the structures immediately inferior to the heart, such as the left lobe of the liver, resulting in severe signal loss

and overestimation of ADC.¹¹ Cardiac gating seems intuitive to reduce cardiac motion effects in the liver, but some authors have found it difficult to find a phase of the cardiac cycle that yields diffusion-weighted images free of signal dropout artifact.¹² Moreover, the combination of respiratory and cardiac gating will significantly prolong scan time to clinically unfeasible levels. Low-*b* value images are less prone to cardiac motion-induced signal loss and are therefore invaluable for lesion detection in susceptible areas.¹³

Bulk motion from bowel peristalsis can be reduced by administration of antiperistaltic drugs (e.g., hyoscine butylbromide and glucagon). However, these are not routinely administered for the evaluation of the upper abdominal viscera.

CHOICE OF *b* VALUES

There is no clear consensus on the precise number and magnitude of *b* values that should be used for abdominal DWI. Considerations include the target organ being evaluated, the image SNR, and whether DWI is primarily used for qualitative or quantitative analysis. For ADC quantification, three or more *b* values are generally recommended, with one being a lower *b* factor (≤ 100 s/mm²) and one being a higher *b* factor (> 500 s/mm²). Additional *b* values can be considered to increase the accuracy of ADC estimation or if IVIM parameters need to be extracted with biexponential modeling.¹⁴ Increasing the number of *b* values results in increase in the imaging time. Some researchers now favor omitting *b* = 0 s/mm² in their ADC calculations to obtain perfusion-insensitive values for comparison between serial measurements.

Image Interpretation

QUALITATIVE ASSESSMENT

The source *b*-value diffusion-weighted images and the ADC maps are both useful for visual assessment. The degree of signal attenuation from water molecules at high *b* values is less in areas of impeded diffusion (in other words, these water molecules produce higher signal on native high-*b* value images). Most pathologic processes, such as tumors, inflammation, and infection, show greater impeded water diffusion compared with normal tissues and thus return higher signal on diffusion-weighted images.

In the abdomen, native *b*-value diffusion-weighted images are used for detection of lesions and pathologic changes because of their excellent suppression of the normal background signal, which increases the conspicuity of tumors and inflammatory processes. Even with minimal diffusion weighting, the signal from vasculature structures is suppressed ("black blood"), and intrinsic fat suppression of diffusion-weighted sequences widens the dynamic range considerably. On low-*b* value images, there is high lesion-to-background contrast, good anatomic information, and fewer eddy current-induced distortions.¹³ However, a "T2 shine-through" effect is present because of the preservation of signal in areas with prolonged T2 relaxation times (e.g., contents of the gallbladder, cystic or mucinous lesions). The use of a high-*b* value image (e.g., *b* = 1000 s/mm²) decreases the relative contribution of T2 signal intensity to diffusion-weighted images, and the T2 shine-through effect may be mitigated if not removed completely. Several investigators have relied on a very high-*b* value approach for detection

of lesions (e.g., *b* value > 1000 s/mm²) in other parts of the body,^{15,16} although this approach has not been shown to confer additional advantages in abdominal diseases.

Inspection of the corresponding ADC map will usually distinguish areas of true impeded diffusion from areas of T2 shine-through. Areas of true impeded diffusion have lower absolute ADC values and by convention appear "dark" on the ADC maps, whereas areas of T2 shine-through have high ADC values and appear "bright." Even when the ADC maps are not available, the reviewer may infer the degree of impeded diffusion on the basis of relative signal attenuation at different *b* values. This concept is illustrated in Figure 69-3B.

However, the diffusion-weighted images should always be interpreted in conjunction with their morphologic counterparts. The background anatomy is better demonstrated on conventional MR sequences, allowing localization of any diffusion abnormality and exclusion of normal and physiologic causes of impeded diffusion. Many of the pitfalls of DWI interpretation detailed later in this section can be avoided by correlation with the morphologic images. Some have proposed a "fusion" approach to image assessment, whereby the functional diffusion information is fused with morphologic data, similar to the creation of positron emission tomography/computed tomography images.

QUANTITATIVE ASSESSMENT

ADC maps are postprocessed representations of the ADC values calculated for each voxel from the source *b*-value images. The mean or median ADC values in areas of interest are derived by drawing regions of interest on these parametric maps. These values can aid lesion characterization as well as provide clues to tissue microstructure, for example, in liver cirrhosis. Lower ADC values imply greater impeded water mobility. However, as ADC values can be dependent on a multitude of scan parameters, there has been difficulty in prescribing a cutoff value between benign and malignant or pathologic and nonpathologic. Reported ranges of ADC in abdominal organs are presented in Table 69-3 for reference.¹⁷

One of the most promising developments in DWI is the use of ADC as a quantifiable biomarker for response assessment. In

TABLE 69-3
Reported Normal Ranges of Apparent Diffusion Coefficient Values for Abdominal Viscera

Organ	Values in Organs without Disease ($\times 10^{-3}$ mm ² /s)	Values in Diseased Organs ($\times 10^{-3}$ mm ² /s)
Liver	1.55 \pm 0.30 to 1.63 \pm 0.31	Cirrhosis 1.45 \pm 0.13 to 1.60 \pm 0.19
Kidney	2.60 \pm 0.32 to 2.67 \pm 0.29	Chronic renal failure 2.11 \pm 0.25 to 2.15 \pm 0.30
Pancreas		Chronic pancreatitis
Head	1.82 \pm 0.40	1.71 \pm 0.20
Body	1.81 \pm 0.41	1.67 \pm 0.17
Tail	1.65 \pm 0.37	1.58 \pm 0.39
Spleen	1.26 \pm 0.23	
Gallbladder	3.50 \pm 0.51	

Modified from Yoshikawa T, Kawamitsu H, Mitchell DG, et al: ADC measurement of abdominal organs and lesions using parallel imaging technique. *AJR Am J Roentgenol* 187:1521–1530, 2006.

general, therapy response is associated with significant increases in tumor ADC, which can be seen as early as within the first week after therapy. The ADC increase is postulated to be due to cellular damage leading to necrosis¹⁸ and has been demonstrated in a variety of tumors, including breast, cervical, prostate, and liver cancers.¹⁹⁻²³ One of the advantages of obtaining longitudinal measurements of ADC is that changes are detected earlier than morphologic changes, potentially allowing earlier assessment of treatment response and potential alterations to management. Baseline ADC measurements are also being investigated as pretreatment predictors of the effectiveness of tumor therapy because diffusivity reflects tissue cellularity, microcirculation, and necrosis, which affect response to chemotherapy. More sophisticated methods of quantitative ADC analysis currently under research include ADC histogram analysis, IVIM analysis, and even textural analysis, but these are beyond the scope of this chapter.

IMAGING ARTIFACTS

Artifacts Related to Echo Planar Imaging

Most DWI for abdominal clinical applications is performed by single-shot echo planar imaging–based sequences. This ultrafast method of k-space acquisition requires large gradient reversals and results in accumulation of phase shift errors because of the prolonged readout. This results in eddy current–induced geometric distortions, image shearing, and Nyquist or N/2 ghosting (Fig. 69-5).⁵ These effects are even more pronounced at higher field strengths because of greater nonuniformities in the magnetic field (B₀), greater diamagnetic susceptibility effects, and shorter T2* relaxation time. On modern scanners, improvements in hardware and sequence optimization have reduced these artifacts. Multishot imaging techniques are being explored, which may further reduce artifacts in the future.

Susceptibility-Related Signal Loss

Diffusion-weighted sequences are prone to susceptibility effects because of the echo planar readout. Hypointensity on DWI may be due to T2 or T2* shortening from abnormal iron deposition, hemorrhage, and inflammation²⁴ (so-called T2 dark-through or T2 blackout). ADC measurements in such areas may be

spuriously low.²⁵ In the abdomen, gas-filled viscera such as bowel and structures close to the lungs can also produce spuriously low or high signals, resulting in missed lesions or false positives. Pathologic iron depositions in the abdominal viscera (most commonly in the liver) and metal implants are other potential sources of susceptibility that could obscure lesion detection.

Physiologic Motion

Ultrafast methods of MRI such as EPI are resistant to but not invulnerable to physiologic motion. Motion degrades image quality in two ways, depending on when it occurs during the scan. Motion during data acquisition introduces additional phase terms, whereas motion between acquisition intervals causes inconsistencies in the data before and after the movement. In both cases, the decreased coherence of the acquired signals produces ghosting, blurring, and lower image SNR. Motion-related data inconsistencies also make ADC assessment of small target lesions inaccurate.

In the abdomen, the main causes of bulk motion are respiratory motion, cardiac motion, and peristalsis. Strategies to minimize the effects of these in the abdomen have been discussed earlier. It is particularly difficult to compensate for the spin dephasing from cardiac pulsation that results in signal loss in the left liver lobe. This decreases the detectability of lesions and impairs the reliability of ADC measurements in the left lobe immediately inferior to the heart.

DIAGNOSTIC PITFALLS

T2 Shine-Through

Tissues with long intrinsic T2 relaxation times (such as free water) may appear hyperintense on diffusion-weighted images even at high b values. This may be falsely ascribed to impeded water diffusion. Comparison with ADC maps or the exponential images (formed by taking the ratio of a diffusion-weighted image divided by an unweighted image from the same image series and slice position) helps avoid this pitfall. In cases of true impeded diffusion, the region of increased DWI signal will demonstrate low ADC values compared with T2 shine-through, which would return a relatively high ADC value.

Figure 69-5 Diffusion-weighted image (b0) through the pelvis obtained with single-shot echo planar imaging technique. Note the geometric distortion, which is especially pronounced at the air-skin interface (dotted line). An artifactual exaggerated concavity is also seen at the posterior border of the prostate. The T2 morphologic image is shown for reference.

Figure 69-6 Diagnostic pitfall of diffusion-weighted imaging. Axial images of the distal rectum in a 64-year-old woman with mucinous rectal carcinoma. The tumor (*) is markedly hyperintense on the T2-weighted images, characteristic of mucinous histology. The high-*b* value diffusion-weighted image (b750) shows very little tumor signal, and the apparent diffusion coefficient (ADC) is high because of the large proportion of freely diffusing water molecules within extracellular mucin deposits.

Normal and Benign Structures Showing Impeded Diffusion

Certain physiologic tissues appear hyperintense on DWI even at high *b* values because of their intrinsic hypercellularity. These include the spleen, lymph nodes, ganglia, spinal cord, bowel mucosa, endometrium, testes, and ovaries. On occasion, tiny foci (1–2 mm) of impeded diffusion are detected on *b*-value images that are difficult to correlate with structures on corresponding morphologic sequences. These may be due to small nerves or venules, which are benign. Apart from malignant or inflammatory processes, benign tumoral lesions with high cellularity, such as liver adenomas, focal nodular hyperplasia, and sclerosed hemangiomas, may show varying degrees of impeded diffusion as well.

Tumors Showing Unimpeded Diffusion

Lesions with mucinous or cystic contents are a potential pitfall on DWI as there is relatively unimpeded diffusion of their internal contents, whereas the cellular portion of tumor may not be evident or is confined only to the lesion wall (Fig. 69-6). Hypocellular tumors, such as low-grade tumors, may not be depicted on DWI. Tumors or abscesses that have been treated may also not show impeded diffusion, but this allows DWI to be used as a marker for treatment response. Knowledge of the relevant clinical history is important, particularly the histologic subtype and treatment history at image interpretation.

Pitfalls of Quantitative Assessment

An important challenge to overcome is the implementation of quantitative ADC measurements in a multicenter setting across different imaging platforms. However, it is encouraging that in well-controlled imaging studies, ADC quantification shows good measurement reproducibility, with coefficient of repeatability as low as 8% to 10% being achievable. Furthermore, interscanner measurement variability of ADC was shown to be 12% across scanners using analogous imaging parameters.²⁶

Radiology departments should verify their MR scanner ADC measurement reproducibility and standardize their own protocols to enable pretreatment and post-treatment ADC measurements to be obtained with confidence in the assessment of

therapeutic response.²⁷ Pooled analysis of data acquired from different centers using analogous technique may be performed by adapting the measurement reproducibility of the worst-performing platform to determine the threshold of significant ADC change. Clearly, such an approach needs to be verified in future clinical trials.

Another potential confounding factor in quantitative ADC assessment is the variability in defining the size and position of the region of interest. This can particularly be a problem for very small residual tumors after therapy. The variations in regions of interest have been shown to have a significant effect on tumor ADC values and interobserver variability.²⁸ The analysis of heterogeneous lesions with DWI can also be challenging as summary values, such as mean or median ADC, may not be representative of the underlying changes. For this reason, more sophisticated methods of data analysis are now being evaluated to better describe lesion heterogeneity and the heterogeneity of tumor response.

In summary, diagnostic characterization with DWI requires integration of morphologic sequences and clinical information and awareness of the artifacts and pitfalls associated with the technique.

Clinical Application in the Abdomen

DWI is useful in a broad spectrum of diseases in the abdomen as the most common pathologic processes, such as neoplasia, inflammation, and infection, alter their microenvironments in such a way as to impede water diffusion. Currently, the most common applications of DWI of the abdomen are for disease detection and disease characterization. However, there is increasing evidence that the quantitative parameters obtained from DWI are also helpful in assessment of response to treatment and as a potential predictive biomarker.

LIVER

Lesion Detection

The background signal suppression in diffusion-weighted images results in excellent conspicuity of focal liver lesions and high lesion-to-background contrast. This coupled with the fact

that the SS-EPI technique used for DWI is inherently less vulnerable to respiratory motion-related blurring provides for a robust sequence for lesion detection. This has been shown in many publications that have demonstrated DWI to be more sensitive in detecting metastases than conventional T2-weighted imaging and at least comparable to extracellular gadolinium contrast-enhanced sequences.²⁹⁻³⁴ A combination of DWI with hepatocellular contrast agents appears to provide the best performance for detection of metastases,³⁵ and the sequence is particularly helpful for detection of lesions less than 10 mm (Fig. 69-7).

DWI may also improve the detection of hepatocellular carcinomas (HCCs). A meta-analysis showed DWI sensitivity to be 81% with 89% specificity, comparable to that of imaging with conventional gadolinium-based contrast agents.³⁶ However, some authors have found DWI to be less sensitive than conventional contrast-enhanced T1-weighted imaging.³⁷ Missed lesions arise in a fibrotic or cirrhotic liver, which creates a background of limited water diffusivity, or are well differentiated, thus diminishing the contrast between lesion and background. The sensitivity of DWI for HCC decreases with increasing cirrhosis³⁸ and lower histopathologic tumor grades.³⁹

Although DWI has not been officially incorporated into the American Association for the Study of Liver Diseases or European Association for the Study of the Liver guidelines on HCC diagnosis, it has been shown to be useful for the diagnosis of hypovascular HCCs when it is interpreted in conjunction with the hepatocellular contrast agents.⁴⁰ Hyperintensity on diffusion-weighted images and hypointensity in the hepatocellular phase imaging (using Gd-EOB-DTPA) favors the diagnosis of HCC over dysplastic or regenerative nodules. Whereas DWI is certainly a useful adjunct, there are insufficient grounds to recommend DWI as a replacement for contrast-enhanced imaging for HCC diagnosis.

Lesion Characterization

DWI is able to distinguish reliably between cystic and solid lesions as cysts show signal suppression at higher b values and return very high ADC values. However, the technique has been less successful at differentiating between benign and malignant solid lesions as all solid lesions appear relatively high signal on DWI, and there is substantial overlap of the ADC values between benign cellular lesions (such as focal nodular hyperplasia and adenomas) and malignant lesions.^{41,42} Moreover, any prescriptive ADC cutoff is itself vulnerable to erroneous lesion

Figure 69-7 Hepatic metastases from colorectal carcinoma. Top panel, Diffusion-weighted image (b500) demonstrates high contrast of lesion (arrowheads) to background liver. The apparent diffusion coefficient (ADC) map shows hypointensity of the wall of each lesion, indicating that viable hypercellular tumor is at the periphery of the lesion, whereas necrotic tumor tissue is in the core. Note the presence of Nyquist ghost artifact (arrow) shifted from the true image by half of the field of view. Bottom panel, left, Hepatocellular phase image obtained 20 minutes after injection of a hepatocellular-specific agent showing relative hypointensity of the metastases (arrowheads); right, T2-weighted image for correlation.

classification because of the variability of ADC quantification. For this reason, one should combine DWI with conventional morphologic MR images for optimal assessment.

Interestingly, liver abscesses return markedly low ADC values because of cellular and viscous debris as well as exudates within the abscess cavity. This can be helpful in distinguishing them from necrotic or cystic tumors, which have necrotic central portions with high ADC.⁴³ Furthermore, the wall of an abscess is often isointense to liver parenchyma, whereas the wall of a cystic or necrotic tumor is hyperintense at DWI owing to its cellularity. However, early abscess formation may be associated with elevated ADC values, thus leading to misinterpretation.⁴⁴

Assessment of Tumor Response to Treatment

It is intuitive that ADC should increase with response to therapy because of cell death and reduced tumor cellularity. Indeed, tumor ADC increase among responders has been observed in several studies with liver metastases and HCC.^{22,45,46} The ADC change is observed earlier than morphologic alterations and as early as 3 days after therapy.⁴⁷ An increase in ADC has been observed in responders of both systemic treatment (chemotherapy) and local-regional therapies (radiofrequency ablation and chemoembolization). However, the exact evolution of ADC after treatment is complex because of concurrent processes, such as acute cell swelling, fibrosis, and perfusional changes, that may affect the diffusion coefficients.

It has been reported that colorectal metastases with high pretreatment ADC values respond poorly to chemotherapy.^{45,48} This may be attributed to more necrotic tumors, which infer a more aggressive phenotype or confer treatment resistance due to diminished drug penetration to the center of the tumors. However, studies correlating pretreatment ADC and long-term clinical outcomes are lacking.

Diagnosis of Liver Fibrosis and Cirrhosis

The noninvasive diagnosis of liver fibrosis and cirrhosis is challenging with conventional MRI as changes are apparent only when fibrosis is relatively advanced. The ADC values obtained by DWI in cirrhotic livers are significantly lower than those in nonfibrotic livers,⁴⁹⁻⁵¹ but distinguishing between the different grades of fibrosis with DWI has been difficult because of the substantial overlap of ADC values between fibrosis grades and the relatively narrow dynamic range of the ADC values in this disease setting. The impeded diffusion observed in cirrhosis has been suggested by IVIM analysis to be in part due to reduction in capillary perfusion.^{52,53}

PANCREAS

Diffusion-weighted MRI has been used to detect pancreatic lesions and to distinguish between solid and cystic pancreatic lesions. Pathologic entities such as pancreatic adenocarcinoma, pancreatic neuroendocrine tumors, solid pseudopapillary tumors of the pancreas, acute pancreatitis, and autoimmune pancreatitis all show impeded diffusion.⁵⁴⁻⁵⁷ Consequently, differentiation between these entities by DWI has been less successful because of substantial overlap in their ADC values. Despite initial enthusiasm, ADC quantification has not been successful in differentiating between pancreatic adenocarcinoma and mass-forming pancreatitis. More recently, the use of IVIM analysis has shown that the perfusion fraction of

pancreatic cancer is lower compared with normal pancreas or mass-forming pancreatitis. However, it is not yet practical to implement this technique in the routine clinical setting.^{58,59}

The conspicuity of pancreatic adenocarcinoma on DWI is also variable. In one series of 80 patients with pancreatic adenocarcinoma,⁵⁵ only about half of pancreatic adenocarcinomas were hyperintense and clearly demarcated from the surrounding pancreatic parenchyma, although overall about 80% of the pancreatic cancers were hyperintense. This was thought to be related to tumor-associated pancreatitis affecting the regions of the pancreas distal to the tumor, which resulted in reduced contrast differentiation between tumoral tissue and inflamed pancreatic parenchyma because both processes impeded diffusion (Fig. 69-8).

With regard to cystic lesions of the pancreas, such as mucinous cystic neoplasm, serous cystadenomas, and intraductal papillary mucinous neoplasms, these demonstrate elevated ADC values. Studies that aimed to differentiate malignant from benign cystic pancreatic lesions have met with limited success,⁶⁰ although it is conceivable that DWI may be able to demonstrate solid components within a cystic pancreatic lesion, such as when there is malignant transformation within an intraductal papillary mucinous neoplasm.

GALLBLADDER

Ultrasound remains the initial investigation of choice for diagnosis of gallbladder disease. However, with the ubiquity of DWI in abdominal MR protocols, a few studies have retrospectively examined the performance of DWI in this area. As can be expected, gallbladder carcinomas show low ADC values, signifying impeded diffusion.⁶¹⁻⁶³ However, it may not always be possible to distinguish gallbladder carcinoma from other polypoidal lesions, adenomyomatosis, and hyperplastic polyps or adenomas.^{63,64} There have been no large-scale studies to date of the findings of acute cholecystitis on DWI, but this remains a potential cause of a false-positive diagnosis of malignant disease. In some patients in whom gas-filled large bowel abuts the gallbladder, EPI-related artifacts might cause spurious signal changes, which confound evaluation of the gallbladder.

SPLEEN

There are very few published studies on the clinical utility of DWI in the spleen. This is because the spleen is hypercellular and therefore shows substantial impeded diffusion and inherently high signal intensity on high-*b* value sequences, rendering any cellular lesions within it less conspicuous. The spleen has been used as an internal reference organ for normalization of ADC values,⁶⁵ an approach favored by some authors but that has inherent limitations. ADC normalization is more susceptible to image noise, and the ADC value of the spleen may not be invariate with antitumor therapies. Interestingly, some studies suggest that ADC values in the spleen may correlate with the severity of liver fibrosis and cirrhosis.^{66,67}

LYMPH NODES

DWI is exquisitely sensitive for the detection of lymph nodes, both normal and pathologic. As even normal and reactive lymph nodes are densely packed with lymphoid elements, they return high signal intensity on diffusion-weighted images. DWI

Figure 69-8 A 70-year-old man with pancreatic tail glucagonoma. Axial diffusion-weighted images (b100 and b750) show the conspicuity of the tumor (arrow) and the multiple hepatic metastases, which show restricted diffusion. Note that the normal spleen also returns a low apparent diffusion coefficient (ADC) value similar to that of tumor because of its inherent hypercellularity.

often reveals normal lymph nodes that are not apparent on other morphologic sequences.⁶⁸

Most studies have shown that malignant nodes return lower ADC values compared with benign lymph nodes,⁶⁸⁻⁷⁰ which may improve size and morphologic criteria for nodal classification. Although there is a distinct trend toward lower ADC values in malignant nodes,⁷¹ there remains a wide range of ADC values in both categories.^{72,73} This makes it difficult to confidently classify any single node prospectively as benign or malignant. The limited spatial resolution of DWI also hinders the accuracy of ADC measurements of small nodes because of partial volume effects. At present, DWI is best used in detection of abdominal nodes, and characterization should be made in conjunction with morphologic sequences. However, the combination of DWI with ultrasmall iron oxide particle-enhanced imaging⁷⁴ shows substantial promise in the detection of lymph node metastases.

PERITONEUM

Small-volume metastatic deposits in the peritoneum or even large peritoneal masses can be missed with computed tomography or conventional MR sequences because they are frequently isodense or isointense with adjacent bowel loops and vessels, affording little contrast to enable their detection. The images on DWI provide effective background suppression in the abdomen by a combination of fat suppression and nulling the signal from bowel viscera and mesenteric vasculature. Any ascites that may be present will be of low signal intensity on high-*b* value images. Therefore, even small-volume peritoneal disease stands out as hyperintense foci in the abdomen.

Several studies have corroborated the sensitivity of DWI for depiction of peritoneal tumors,⁷⁵⁻⁷⁷ with sensitivity ranging from 84% to 90% when it is used in conjunction with conventional MR sequences. The technique has also been used with gadolinium-enhanced imaging to accurately predict the peritoneal cancer index before surgery in patients undergoing evaluation for cytoreductive surgery.⁷⁸ This may potentially differentiate patients who are good surgical candidates from those who may be candidates for neoadjuvant chemotherapy to reduce tumor burden (Fig. 69-9).

GASTROINTESTINAL TRACT

Detection and Characterization of Disease

DWI has been successfully applied in the gastrointestinal tract for detection of malignant lesions as well as bowel inflammation. The speed of *k*-space acquisition with the SS-EPI technique makes bowel peristalsis less of an issue compared with other MR sequences, in which shot-to-shot differences produce blurring of moving structures such as bowel.

DWI has been shown to be able to depict tumors in the esophagus, stomach, small bowel, and large bowel.^{15,72,79-84} High-*b* value diffusion-weighted images are the most effective in this regard as hypercellular tumors appear hyperintense, with corresponding low ADC values. It is particularly useful in regions where pseudothickening of bowel wall due to muscle contraction or benign inflammatory processes may mimic malignant neoplasms. For example, in the stomach, low ADC values have helped differentiate gastric wall thickening due to malignant disease from benign causes, such as gastritis and portal gastropathy.⁸⁰ In the ampullary region, DWI improves the diagnosis of ampullary carcinomas over

Figure 69-9 A 52-year-old woman with ovarian carcinoma and peritoneal carcinomatosis. The high- b value diffusion-weighted image (b900) shows excellent contrast between the hyperintense tumor coating the peritoneal lining (arrows) and ascites in the pelvis, which is almost completely attenuated in signal. The large primary ovarian mass (*) is also seen on the b900 image. In comparison, the true extent of peritoneal disease is easily underestimated on morphologic T2-weighted and computed tomography (CT) images. ADC, Apparent diffusion coefficient.

conventional MR sequences as it is able to differentiate malignant from benign papillary lesions, such as papillary stenosis and papillitis.⁸¹

A few caveats regarding the use of DWI in the gastrointestinal tract are worth noting. Early tumors (T1 and T2) are generally difficult to detect. In the esophagus, there is particularly poor sensitivity of DWI for detection of primary tumors (49% in one series⁷²). This has been attributed to signal loss from adjacent “incoherent” cardiac motion. Another problem is the hyperintensity of viscous bowel content, which may mask underlying mucosal lesions. Gaseous contents within bowel can also cause susceptibility artifacts that can obscure pathologic changes or produce spurious signals. Last, the ability of DWI to detect premalignant lesions, such as small polyps, has thus far been disappointing.⁸³ This may be related to current technical limitations with DWI resolution as well as the tissue architecture of adenomas, which may be less cellular than their malignant counterparts.

Assessment of Treatment Response and Disease Recurrence

In rectal cancer, MRI performed after neoadjuvant chemoradiotherapy can be challenging to interpret with morphologic sequences (T2-weighted imaging) because it is frequently difficult to differentiate between post-treatment fibrosis and residual tumor. The addition of DWI to T2-weighted imaging has been shown to be invaluable in post-treatment imaging as residual tumor will be expected to show impeded diffusion, whereas fibrosis is relatively hypointense on high- b value images. DWI has been shown to improve diagnostic performance in the prediction of tumor clearance in the mesorectal fascia,⁸⁵ assessment

of complete pathologic response,⁸⁶ and detection of areas of viable tumor⁸⁷ (Fig. 69-10).

ADC as a Prognostic Biomarker

To date, the value of ADC as a prognostic quantitative biomarker in patients with rectal cancer is unclear. In one series, lower tumor ADC values were found to correlate with involvement of the mesorectal fascia, higher nodal stage, and poorer histologic differentiation of the neoplasm.⁸⁸ Studies investigating the role of pretreatment tumor ADC as a prognostic factor in terms of prediction of response to chemoradiation have generally shown that tumors with lower ADC values respond more favorably.^{18,89} A possible hypothesis for this is that nonresponding tumors have higher ADC values due to internal necrosis and are therefore hypoxic and poorly perfused, resulting in a poor response to chemotherapy.

Utility in Nononcologic Bowel Disease

DWI has also been successfully applied to the imaging of inflammatory bowel disease. DWI hyperintensity is associated with active inflammation in ulcerative colitis and Crohn's disease.^{90,91} The sequence facilitates detection of complications, such as abscesses, fistulas, and stenotic segments,⁹² and provides sensitivity comparable to that of contrast-enhanced MRI. Impeded diffusion in inflamed bowel may result from reduced extracellular space secondary to cell swelling or increased cell density caused by migration of lymphocytes into the bowel wall. The absence of need for ionizing radiation, intravenous contrast administration, and bowel preparation are major advantages of DWI in regular imaging follow-up for this patient population.

Figure 69-10 Changes in diffusion-weighted imaging in response to treatment. *Top panel,* Pretreatment appearance of the distal rectal adenocarcinoma (arrow). The primary tumor is hyperintense on diffusion-weighted imaging (b750) and hypointense on the apparent diffusion coefficient (ADC) map, indicating restricted diffusion. *Bottom panel,* Appearance 3 months after chemoradiotherapy. The tumor shows marked hypointensity on the T2-weighted image, indicating fibrosis. The mass is isointense to the surrounding rectal wall on diffusion-weighted images, as would be expected for response due to loss of cellularity.

Low- b value imaging may be used to study alterations in bowel peristalsis, such as in the diagnosis of bowel strangulation.⁹³ In normal bowel showing motility, the turbulent flow of the intraluminal contents results in suppression of their signal at low- b value DWI. In contrast, strangulated bowel segments have severely impaired or absent peristalsis, resulting in relative preservation of signal of their contents.

Future Directions

In the past decade, DWI has been rapidly adopted for the evaluation of abdominal disease. It is a powerful qualitative tool, but the use of quantitative ADC values for disease characterization and tumor response assessment is not fully realized.²⁷

The pathway to technical optimization and standardization has seen developments broadly along two ideologies. One school of thought suggests that all technical details should be strictly prescribed, including all the b values, and implemented rigorously across all scanners. Another school of thought reasons that it may be sufficient to recommend a range and number of b values to be used for the DWI measurements, taking into account the tumor ADC values that are likely to be encountered. The former approach may find difficulties in implementing exactly the same imaging protocol across

different MR systems; these MR systems have different gradient performance, which would affect the choice of scan settings and hence the ADC results. The latter approach may be more practical but may introduce more ADC variability across centers. At the moment, it is probably reasonable that both approaches be pursued to allow us to have a sense of the “best case” versus “worst case” ADC variability that may be encountered in a multicenter setting with these approaches so that an informed decision can be made as to how prescriptive the choice of scan parameters should be to ensure practical comparison across a range of imaging departments.

For ADC data analysis, it is recognized that the summary values of mean or median ADC values may not adequately reflect lesion heterogeneity. New approaches, such as volumetric or histogram ADC analysis, are also being tested that may allow robust comparison of data.^{94,95} However, such complex methods of diffusion-weighted MRI data analysis are not currently available on commercial MRI platforms.

Last but not least, whereas diffusion-weighted MRI has high diagnostic accuracy and utility on its own, it may be combined with other functional MRI techniques, such as dynamic contrast-enhanced MR imaging, MR elastography, or MR spectroscopy. This multi-parametric imaging paradigm has been adopted for prostate imaging and shown to improve diagnostic

performance,⁹⁶ and it would be exciting to see more applications and research developed in the abdomen to further enhance disease assessment.

Summary

Diffusion-weighted MRI provides a unique and effective contrast mechanism for detection and characterization of

abdominal disease that is easily incorporated into standard abdominal imaging protocols.⁹⁷ Optimization of acquisition technique and understanding of its limitations and pitfalls are critical in successful implementation of DWI in clinical practice. Diffusion-weighted images should always be interpreted in the appropriate clinical context and in combination with conventional MR images. It has great potential as a quantitative biomarker, and future developments should consolidate that role.

Clinical Applications

Summary

Perfusion imaging is an exciting new radiologic investigation that allows functional evaluation of tissue vascularity by measuring the changes in the tissue characteristics after administration of intravenous contrast medium (IVCM). Rapid technologic advancements in both computed tomography (CT) and magnetic resonance imaging (MRI) coupled with innovations in postprocessing capabilities have widened the scope of perfusion imaging in a wide range of research and clinical applications.¹⁻¹⁰

Early in its development, perfusion imaging demonstrated significant applications in the evaluation of stroke patients because of its ability to accurately depict the structural and functional status of cerebral vasculature.¹¹⁻¹³ With improved understanding of the tissue vascular physiology, perfusion imaging has been used extensively in various other body applications. In an oncologic setting, perfusion imaging plays a key role not only in the diagnosis and staging of malignant neoplasms but also in prognostic evaluation and monitoring of treatment response in various cancers.^{3,6,9,10,14-27} In addition, the ability of perfusion imaging to evaluate tumor biology and function has a promising role in providing early surrogate biomarkers for treatment response, thereby facilitating customized patient therapeutic options. In this chapter, we review the basic principles of perfusion CT and MRI and discuss their clinical applications in the management of diseases of the abdomen and pelvis.

Basic Principles

Perfusion imaging, either CT or MRI, essentially involves sequential acquisition of images through a particular tissue in

question after the administration of IVCM.^{7,8,22,28,29} After intravenous administration, the contrast medium travels through the vascular system, leaks from the tissue vasculature, accumulates in the tissue, and then diffuses back into the vascular system before being ultimately eliminated through the urinary system.^{7,8,22,28,29} By measurement of the changes in tissue density or signal intensity during the movement of contrast material with sequential images, perfusion CT or MRI is able to estimate various semiquantitative measurements of perfusion, which allows evaluation of the tissue vascularity.^{7,8,22,28,29} Objective measurement of tissue enhancement by placement of region of interest (ROI) over the tissue allows generation of graphs of tissue density or signal intensity versus time, which enables measurement of semiquantitative values.

Perfusion Computed Tomography

Perfusion CT provides estimation of tissue vascularity by measurement of the progressive changes in tissue density after injection of iodinated IVCM. This functional CT technique is usually performed for evaluation of tissue perfusion in day-to-day clinical practice because of its widespread availability and presence of better experience. The speed of image acquisition and round-the-clock accessibility are particularly valuable in a neurologic setting for the evaluation of stroke patients, in whom it allows institution of immediate therapeutic interventions.²¹ The simple linear relationship between iodine concentration and tissue density changes and the easy availability of commercial software for postprocessing render quantification of vascularity easier with CT.^{7,21,22,30} In addition, the routine use of multidetector CT (MDCT) for tumor diagnosis and response assessment makes perfusion CT a preferred choice in an oncologic setting because it allows easier integration into treatment protocols.²¹

TECHNICAL PRINCIPLES

The basic principle of CT perfusion is the depiction of temporal changes in tissue attenuation after intravenous administration of iodine-based contrast medium (Fig. 70-1).²⁹ Tissue enhancement, which refers to increase in tissue attenuation after administration of IVCM, is proportional to the iodine concentration of tissues. Dynamic CT acquisition after IVCM administration thereby allows assessment of tissue enhancement, which represents an indirect measure of tissue vascularity and vascular physiology.²⁹ Tissue enhancement after IVCM administration can be divided into two phases based on distribution characteristics of the contrast medium in the intravascular and extravascular compartments.^{8,29} The initial phase of enhancement or the first pass (usually lasting 30-60 seconds after influx of the

contrast medium) is mainly due to distribution of contrast medium within the intravascular space.^{8,29} In the second phase, tissue enhancement is secondary to distribution of contrast medium between both intravascular and extravascular compartments due to movement of contrast medium from the intravascular to the extravascular compartment across the capillaries.^{8,29} Accordingly, tissue enhancement in the first phase is determined primarily by tissue blood flow and blood volume, whereas capillary permeability to the IVC contributes to enhancement in the later phase.^{8,29} Semiquantitative assessment of tissue perfusion based on dynamic CT acquisition can be accomplished by analytical methods, and the two most commonly used analytical methods are deconvolution and compartmental analysis.^{8,21,22,31}

Both the deconvolution and compartmental modeling methods are broadly equivalent, with few differences in their theoretical assumptions and susceptibility to noise and motion.^{8,21,22,31} Compartmental analysis (single- and

double-compartment methods) is based on the assumption that the bolus of contrast material is retained within the organ of interest at the time of measurement, and this can at times result in underestimation of perfusion values in organs with rapid vascular transit.^{8,21,22,31} Compartmental analysis uses three sets of images for perfusion estimation, including the baseline image and images before and after the maximal rate of contrast enhancement, and is therefore not usually degraded by patient motion.^{8,21,22,31} However, the presence of higher image noise adversely affects perfusion value calculation for the compartmental model, and therefore a higher tube current with lower image frequency is preferred for the dynamic CT technique.^{8,21,22,31}

Deconvolution analysis is based on the use of arterial and tissue time-concentration curves to calculate tissue perfusion and relative blood volumes.^{8,22,32} Although this modeling technique works well for most organs, it might not be suitable for assessing perfusion in organs such as the spleen and kidney, which have complex microcirculations, for which compartmental analysis is preferred.^{8,22,32} Deconvolution methods are suitable for measuring lower perfusion values (<20 mL/min/100 mL); this method tolerates greater image noise because the complete time series of images is included for calculation.^{8,22,32} As a result, deconvolution analysis is particularly beneficial for monitoring treatment response because of its ability to accurately measure lower perfusion values typically seen after successful treatment. The inclusion of the complete series of images, however, renders this method susceptible to image misregistration from patient motion and therefore erroneous calculation.^{8,22,32} As the deconvolution method is less sensitive to noise, it allows use of a lower tube current and permits scanning with higher temporal resolution for dynamic cine CT acquisition.^{8,22,32} The various analytical methods, the acquisition protocols, and the software packages differ between scanner technologies and the commercial vendors (Table 70-1). Nevertheless, irrespective of the technology used, perfusion CT allows estimation of various qualitative and quantitative measures of tissue perfusion.^{8,22,32}

Figure 70-1 Time-attenuation curves showing enhancement characteristics of the artery and the tumor during the first pass and the delayed phase of the perfusion CT acquisition.

PROTOCOL

The perfusion CT protocol needs to be tailored to the clinical objective in question, body part being scanned, mathematical

TABLE 70-1 Comparison of Various CT Perfusion Analytical Models

Mathematical Model	Deconvolution Method	Two-Compartment Model	Slope Method
Vendors	GE Healthcare	Siemens	Philips, Toshiba, Siemens
Basic principle	Uses arterial and tissue time-concentration curves to estimate tissue perfusion	Based on Patlak analysis and assumes one-way transfer of contrast medium from IVS and EVS proportional to blood clearance constant	Perfusion is estimated as a maximum slope of tissue concentration curve normalized to maximum arterial enhancement
Parameters measured	BF, BV, MTT, PS	BV and permeability	BF, MTT, time to peak enhancement
Advantages	The perfusion parameters can be calculated by a single CT study	Simple analysis Efficient in calculation of rate constant value	Short scan duration Assumption of no venous outflow and no recirculation; less sensitive to movement
Limitations	Partial volume averaging correction required	Based on assumption that back-flux of contrast medium from EVS to IVS is negligible in the initial 1-2 minutes	Sensitive to image noise

Data from references 4, 5, 8, 17, 21, 29, 30, 70, and 71. Adapted from reference 21.

BF, Blood flow; BV, blood volume; EVS, extravascular space; IVS, intravascular space; MTT, mean transit time; PS, permeability–surface area product.

modeling technique employed, CT scan configuration, and radiation dose considerations.^{8,21,22,32,33} A typical dynamic CT protocol consists of a preliminary noncontrast scan followed by a dynamic acquisition performed after administration of IVCN. The noncontrast CT scan serves as a localizer for selecting the appropriate tissue area to be included in the dynamic CT acquisition. A 2- to 4-cm area of tumor tissue is routinely selected for dynamic scanning on the basis of the scanner configuration (16-slice or 64-slice CT scanner).²¹ With the introduction of 128-slice to 320-slice MDCT scanners, larger areas of tumor tissue (8-16 cm) can be interrogated for assessment of tissue perfusion.^{21,34} Several techniques have been introduced to allow perfusion imaging of a volume of tissue or entire organ, including axial shuttle mode (repeated axial scans at two adjacent table positions in a to-and-fro manner to double detector coverage) and helical shuttle mode (continuous bidirectional table movement with variable pitch).³⁴⁻³⁸

The dynamic CT acquisition consists of a first-pass phase, a delayed phase, or both, depending on the pertinent physiologic parameters that need to be analyzed and the tissue in question.²¹ The first-pass phase or the initial cine phase consists of CT images acquired for a total of 40 to 60 seconds after the injection of IVCN.^{8,29-31} For obtaining permeability measurements, a second delayed phase ranging from 2 to 10 minutes follows the first phase.^{8,29-31} In the first-pass phase, the MDCT images are acquired every 1 to 3 seconds; in the second phase, the images are acquired every 5 to 15 seconds.^{8,29-31} A key consideration for optimal evaluation of tissue perfusion is the IVCN bolus used for dynamic CT acquisition (Table 70-2). An additional consideration in dynamic CT evaluation of the upper abdomen

is the need for appropriate breath-holding instructions to patients to limit the potential deleterious effects of motion on estimated perfusion values.^{8,21,29-31} Some authors recommend use of motility-inhibiting agents, such as glucagon, to limit peristaltic movements of bowel during image acquisition.^{1,19-21,39}

POSTPROCESSING

The dynamic CT data obtained after a perfusion CT study are processed on dedicated workstations using specific vendor-based perfusion software.²¹ The postprocessing of the CT perfusion data generates colored parametric perfusion maps. Quantitative tissue perfusion measurements are then obtained from these perfusion maps by ROI placement over the tissue in question. The various quantitative perfusion parameters estimated depict various aspects of tissue or tumor vascular physiology²¹ (Table 70-3). With the increasing use of CT perfusion in various body applications, several non-vendor-based software models are available that allow estimation of tissue perfusion irrespective of the method of scanning.

CLINICAL APPLICATIONS

Perfusion CT has been established as a valuable technique for estimation of tissue vascularity. The validity and reproducibility of this functional CT technique have been proved in several animal and human studies and tested against other techniques, such as xenon washout methods.^{12,21,40-42} Early studies have demonstrated the value of this technique in quantifying tissue perfusion in solid visceral organs such as liver, pancreas, spleen, and kidney.* Ever since, perfusion CT has found a wide range of applications in oncology, such as determining tumor biology including lesion characterization, risk stratification and staging, monitoring response to various treatment regimens (chemoradiation and antiangiogenic drugs), and predicting treatment outcome.^{21,22,33,44} In addition to the overwhelming amount of research performed in oncology, this technique has also been explored in the assessment of tissue perfusion in various non-oncologic applications, such as in patients with cirrhosis and renal artery stenosis.

Tumor Biology

One of the key elements of tumor physiology that influences the aggressiveness of tumors and their response to treatment is

*References 9, 10, 15, 19-21, 24, 27, 43.

TABLE 70-2	Technical Parameters of a Typical CT Perfusion Protocol
Kilovoltage*	100-120
Milliamperes-seconds* (mAs)	50-150
Iodine concentration† (mg I/mL)	370-400
Contrast bolus (mL)	40-70
Injection rate‡ (mL/s)	4-10
Scan delay (s)	5-10

Data from references 8, 21, 29-31.
*Lower kilovoltage peak and milliamperes-seconds are recommended to reduce the radiation exposure.
†A higher iodine concentration of 370 mg I/mL is preferred because of the linear relationship between iodine concentration and tissue enhancement.
‡Higher injection rates are preferable to maximize tissue enhancement and to improve signal-to-noise ratio.

TABLE 70-3	Various CT Perfusion Parameter Terminologies for Description of Tissue Vascular Physiology		
Perfusion Parameter	Definition	Marker (in Oncology)	Units
Blood flow or perfusion (BF)	Flow rate through tissue vasculature in the region of interest	Tumor vascularity	mL per 100 g/min
Blood volume (BV)	Volume of blood flowing within the tissue vasculature in the region of interest	Tumor grade	mL per 100 g
Mean transit time (MTT)	Average time taken to travel from artery to vein	Tumor vascularity	Seconds
Permeability-surface area product (PS)	Total flux from plasma to interstitial space	Perfusion pressure	mL per 100 g/min
Time to peak (TTP)	Time from arrival of the contrast medium in major arterial vessels to the peak enhancement	Immature leaky vessels	Seconds
Peak enhancement intensity (PEI)	Maximum increase in tissue density after injection of contrast medium	Perfusion pressure	
		Tissue blood volume	HU

Data from references 4, 5, 8, 17, 21, 29, 30, 70, 71. Adapted from reference 21.

the status of tumor microvasculature (neoangiogenesis).^{*} Tumor angiogenesis refers to the development of new blood vessels in the tumor, resulting in vascularization.^{*} Histopathologic markers, such as tumor microvessel density count, are established markers of tumor angiogenesis. Despite the “gold standard” attributes of microvessel density, it is invasive to obtain tissue, often in regions that are difficult to approach, and fraught with sampling error. Moreover, it lacks the functional information about angiogenesis and is often impractical for monitoring of response at several time points. Because the perfusion profile of a lesion on dynamic contrast-enhanced CT (CECT) is a reflection of its underlying vascular signature, CT perfusion can be exploited to predict the status of tissue vascularity and therefore predict tumor biology.^{*} Several studies have demonstrated the role of perfusion CT in evaluating tumor biology, including lesion characterization and assessment of tumor grade.[†]

Several studies have shown significant differences in tissue perfusion values between normal tissue and benign and malignant tumors in the liver, pancreas, and colon.[‡] In general, malignant tumors demonstrate higher perfusion values (increased tumor perfusion and capillary permeability). In bowel, colorectal cancers demonstrate higher tumor perfusion compared with normal colonic wall.^{5,10,39} Higher tumor perfusion can also be used to differentiate between colonic wall thickening in diverticulitis and colorectal cancer.^{5,10,39} In the liver, perfusion CT allows an earlier detection of hepatic metastases because hepatic arterial perfusion in these patients is increased.⁴⁶⁻⁵⁰ The lesions are seen as an area with increased blood flow in comparison to the rest of the liver parenchyma. The baseline tumor perfusion in hepatic metastases can also be used to predict treatment outcome as metastatic lesions with higher perfusion have improved prognosis compared with those with lower perfusion.⁴⁶⁻⁵⁰ In patients with hepatocellular carcinoma (HCC), differentiation from background liver is possible because of the higher perfusion seen in HCC (higher blood flow, blood volume, and permeability–surface area product).^{9,24}

Perfusion CT also aids in evaluating tumor aggressiveness and helps differentiate between well-differentiated and moderately to poorly differentiated tumors.^{9,24} In the pancreas, dynamic CECT allows characterization of hypervascular pancreatic tumors, such as insulinoma, that show higher perfusion.^{15,51} The perfusion measurements of pancreatic neuroendocrine tumors also correlate with histoprosthetic factors.^{15,51} In the prostate, malignant foci have shown considerably increased perfusion values, and this potentially would allow identification of tumor foci, thus enabling targeted radiotherapy with minimal radiation to the surrounding tissues.⁵²

Risk Stratification and Staging

Tumor vascularity is a marker of tumor aggressiveness, and higher tumor vascularity is often indicative of aggressive biology and often associated with a poor outcome compared with less vascular tumors.^{21,33} By depicting the vascular signature of tumors, CT perfusion has been shown to be valuable in risk

stratification and tumor staging.^{21,33} Patients with metastatic renal cell carcinoma with higher baseline tumor perfusion have been shown to have a poor prognosis.⁵³ In patients with rectal cancer, dynamic CECT has been shown to be more accurate and specific than conventional CT in characterizing local invasion.⁵⁴ In HCC, baseline perfusion parameters have been shown to correlate with clinical outcome.^{9,27}

Even in nononcologic settings, perfusion CT has been shown to be helpful in risk stratification. In patients with cirrhosis, perfusion changes depicted on CT correlate well with the severity of chronic liver disease.^{55,56} In patients with acute pancreatitis, perfusion CT has been found to be sensitive for detection of pancreatic ischemia, which demonstrates reduced perfusion values compared with normal pancreas.²⁴ The identification of ischemic areas can help predict the later development of pancreatic necrosis, which has therapeutic implications because its early detection and identification will allow induction of intensive care for these patients at the earliest to prevent infective complications and to improve the prognosis.²⁴ In patients with mesenteric ischemia, dynamic CECT has the potential role of identifying bowel at risk of ischemic injury.

Monitoring Treatment Response

Novel antiangiogenic drugs target tumor neoangiogenesis, which is mediated by circulating factors, such as vascular endothelial growth factor, fibroblast growth factor, and platelet-derived endothelial cell growth factor.^{*} After successful response to therapy, there is a reduction in tumor perfusion, vascularity, and vascular permeability that precedes changes in tumor size.[†] Conventionally, therapeutic response to various treatment regimens has been monitored by serial assessment of tumor burden on CT or MRI according to criteria such as the Response Evaluation Criteria in Solid Tumors (RECIST) or World Health Organization criteria.^{2,44,58} However, these traditional methods of response assessment are not effective in demonstrating early changes after treatment with targeted therapies because the functional and perfusional changes precede morphologic changes.^{2,44,58} An ideal imaging marker for these therapies needs to be noninvasive, reproducible, readily available, and repeatable and should dynamically reflect the microcirculatory function in a living individual.^{2,44,58} Perfusion CT has particularly seen rising utility in monitoring treatment response in various cancers to a number of therapeutic regimens, including chemoradiation and novel antiangiogenic drugs. In addition to monitoring treatment response, dynamic CECT could be used to predict response and prognosis.

After a combined chemotherapy regimen of oxaliplatin and bevacizumab in HCC, CT perfusion demonstrated reduction in tumor vascularity that correlated with clinical response (Fig. 70-2).²⁷ In rectal cancer, after combined chemoradiation including antiangiogenic therapy, a consistent decrease in tumor perfusion (fall in blood flow and increase in mean transit time) was shown on CT (Fig. 70-3).^{10,25,45} There is also evidence that CT perfusion has shown reduction in tumor perfusion after antiangiogenic therapy in renal cell carcinoma and neuroendocrine tumors.^{59,60}

Figure 70-2 CT perfusion images obtained before and after treatment with antiangiogenic agent in a 56-year-old man with hepatocellular carcinoma. Axial contrast-enhanced CT image in the dynamic phase (**A**) shows the avidly enhancing rounded hepatocellular carcinoma in the left lobe; corresponding colored perfusion map (**B**) demonstrates increased blood flow (102 mL/100 g/min). After antiangiogenic therapy, axial contrast-enhanced CT image (**C**) shows reduced enhancement; corresponding colored perfusion map (**D**) demonstrates reduction in the blood flow (15 mL/100 g/min).

Figure 70-3 CT perfusion images obtained before and after treatment with antiangiogenic agent in a 72-year-old man with rectal cancer. Axial contrast-enhanced CT image in the dynamic phase (**A**) shows the avidly enhancing tumor in the rectum; corresponding colored perfusion map (**B**) demonstrates increased blood flow (78 mL/100 g/min). After treatment with bevacizumab, axial contrast-enhanced CT image (**C**) shows reduced enhancement; corresponding colored perfusion map (**D**) demonstrates reduction in the blood flow (20 mL/100 g/min).

Perfusion Magnetic Resonance Imaging

Perfusion MRI is a dynamic imaging technique that allows noninvasive characterization of tissue vasculature after the intravenous administration of a paramagnetic tracer.^{28,61-65} By quantifying the signal changes induced by the tracer in the tissue as a function of time, perfusion MRI allows evaluation of tumor perfusion and capillary permeability.^{28,61-65} Gadolinium-based contrast agents, such as gadopentetate dimeglumine, are frequently used because they have a sufficiently small molecular weight to allow visualization of lesion vasculature.^{28,61-65} Perfusion MRI has several advantages over perfusion CT, including lack of ionizing radiation, superior soft tissue contrast resolution, and improved coverage of anatomy. The additional advantage includes the capability of performing functional imaging techniques, such as diffusion-weighted imaging and magnetic resonance spectroscopy, which provide complementary information in evaluation of tumor physiology and in monitoring treatment response.

TECHNICAL PRINCIPLES

Perfusion MRI involves sequential acquisition of images during the passage of gadolinium-based contrast agents through the particular tissue of interest and measures variations in vessel and tissue enhancement over time.^{28,61-65} It depicts the signal changes induced by gadolinium as it moves through the tissue as a function of time.^{28,61-65} Perfusion MRI or dynamic contrast-enhanced MRI (DCE-MRI) is typically performed with T1-weighted imaging.^{28,61,65} In general, T2-weighted images are not useful because of loss of T2 weighting after extravasation of tracer into the interstitial space despite the strong T2 effects of intravascular tracers.⁶⁵ On the other hand, T1 weighting is not affected by tracer extravasation and therefore allows derivation of permeability measurements by analyzing the slow component of the signal.⁶⁵ For the same reason, the use of protein-bound gadolinium tracers must be avoided to allow permeability measurements.^{28,61,65}

PROTOCOL

The selection of the appropriate DCE-MRI technique should be tailored to the organ under investigation and involves selection of the appropriate MRI sequences, contrast agent, injection protocol, and robust postprocessing software.⁶⁵ Because of improved contrast-to-noise ratio, 3T scanners are generally preferred to 1.5T scanners for perfusion MRI.⁶⁵ A typical MRI perfusion sequence includes a precontrast T1-weighted image followed by a series of T1-weighted images after gadolinium administration.⁶⁵ Data acquisition is started 10 to 20 seconds before the bolus is injected to allow acquisition of a sufficient amount of precontrast data. A typical injection protocol includes injection of 0.1 mmol per kilogram of body weight of gadolinium-diethylenetriaminepentaacetic acid (Gd-DTPA).⁶⁵ The gadolinium agent is generally injected at a rate of 2 mL/s.^{65,66} The bolus of contrast material is flushed with 20 to 30 mL of saline at the same injection rate.^{65,66} The acquisition time is similar to that of CT perfusion; an acquisition time of 1 minute is usually adequate for perfusion measurements, with a longer time for permeability measurements, usually up to 5 minutes.⁶⁵ In tissues with slower enhancement,

longer acquisitions may be required.⁶⁵ A sampling interval of less than 2 seconds is usually recommended for measurement of perfusion because the tracer transit time in the capillary bed is usually in the range of 3 to 5 seconds.⁶⁵ An optimum balance of the sampling interval is necessary as slower sampling permits improved spatial resolution and signal-to-noise ratio.⁶⁵ Lower temporal resolution with longer sampling interval may be used for permeability measurements because the transit times in the extravascular space are longer on the order of minutes.⁶⁵

The DCE-MRI sequences are most commonly either two-dimensional or three-dimensional gradient-echo sequences.⁶⁵ The earliest perfusion MRI sequences had limited number of slices in the two-dimensional sequence because of the need to achieve higher temporal resolution.⁶⁵ However, with the introduction of parallel imaging and faster MRI sequences, three-dimensional gradient-echo sequences are increasingly used.⁶⁵ Multiecho sequences are typically preferred because they eliminate any T2 effects.⁶⁵ Technologic advancements in DCE-MRI leading to shorter echo times and higher field strengths have improved the image quality.⁶⁵ One of the major impediments to perfusion MRI in the abdomen is the adverse effect of breathing motion.⁶⁵ This can be minimized by data acquisition in the breath-hold or triggering mechanism to ensure that the data are always acquired at the same point in the breathing cycle.⁶⁵ Multiple breath-holds are usually necessary, which runs the risk of misregistration between different breath-holds and might affect quantification.⁶⁵ Triggering mechanism can reduce temporal resolution to below the requirements for accurate perfusion measurement.⁶⁵

DATA ANALYSIS

The analysis of the perfusion MRI data sets is usually performed on sophisticated workstations with dedicated perfusion software. The perfusion data set can be interrogated to obtain descriptive parameters, such as time to peak enhancement, area under the curve, or maximum enhancement, by use of the shape and structure of curves, plotting the signal intensity changes as a function of time.⁶¹⁻⁶⁵ More robust evaluation of the tissue vascularity can be obtained by performing quantitative analysis to measure physiologic parameters, such as tissue blood flow, blood volume, and interstitial volume or permeability surface area.⁶¹⁻⁶⁵ Determination of quantitative or descriptive parameters can be done by ROI analysis or voxel-based analysis.⁶¹⁻⁶⁵ ROI analysis involves manually or semiautomatically performing a ROI in the tissue of interest or lesion on one of the parametric maps, and this takes into account the average signal-time curves of all voxels in the ROI and gives the average over the ROI.⁶¹⁻⁶⁵ Voxel-based analysis involves application of the postprocessing algorithm to each individual voxel, which allows depiction of the heterogeneity of perfusion or permeability within the organ or tumor.⁶¹⁻⁶⁵ Motion correction can also be applied at the postprocessing level to account for the misregistration artifacts.⁶⁵ This is performed by coregistration techniques with use of a reference image to apply corrections.⁶⁵ This avoids the tedious process of redrawing the ROI for every individual dynamic image.⁶⁵ The various quantitative perfusion parameters include the blood flow, blood volume, permeability-surface area product, volume transfer constant (K^{trans}), and rate transfer constant (K_{ep}).⁶⁵

CLINICAL APPLICATIONS

The perfusion characteristics of tumors depicted on MRI have been shown to correlate with prognostic factors, such as histologic grade and overall survival.^{61-64,66} Several studies have shown the value of DCE-MRI in monitoring tumor response to therapy and its role as an early indicator of treatment response.^{61-64,66} The studies have been predominantly performed in cancers of the breast, cervix, bowel, liver, lung, and head and neck.^{61-64,66}

Perfusion MRI not only estimates the tissue perfusion but also visualizes the heterogeneity in the angiogenic properties within an individual tumor.^{61-64,66} The determination of heterogeneity within the tumor tissue is crucial in assessing early therapy response and individualizing treatment regimens because it allows identification of a small subpopulation of tumor cells that are resistant to treatment.^{61-64,66} However, generalization of these results is difficult because of the differences in technique and population studied.^{61-64,66}

In a study of perfusion MRI in patients with rectal cancer, George and associates⁶⁷ showed that patients with higher baseline permeability measurements responded better to chemoradiation than those with lower permeability. Mayr and coworkers⁶⁸ showed that perfusion MRI could predict tumor

recurrence on the basis of the enhancement rate within 2 weeks of radiotherapy in cervical cancer patients, with poor enhancement having a high recurrence rate of 78%. Lancaster and colleagues⁶⁹ showed in a study of patients with cervical cancer that small tumors with enhancement showed a better survival (92%) versus larger poorly enhancing tumors (55%). Perfusion MRI has been found to be helpful in detecting residual disease and in predicting early recurrence and identifying patients who are likely to benefit from salvage treatment.⁶¹⁻⁶³ Persistent enhancement at the end of the treatment regimen is more likely to be associated with increased risk of recurrence and poor survival.⁶¹⁻⁶³ In patients with cervical cancer, Boss and coworkers showed that early onset of enhancement after completion of a 6-week course of radiation treatment predicted recurrence and poor survival.^{61,63} Perfusion MRI has been studied as a potential biomarker for antiangiogenic therapy.⁶⁴ Liu and associates, in a study of patients with cancers of the liver and lung, showed that K^{trans} and initial area under the curve had inverse correlation with axitinib plasma exposure.⁶⁴ In HCC, Sahani and colleagues⁶⁶ showed that perfusion MRI is a more sensitive biomarker in predicting early response and progression-free survival after sunitinib therapy compared with RECIST criteria (Fig. 70-4).

Figure 70-4 MR perfusion images before and after sunitinib therapy in a 47-year-old man with hepatocellular carcinoma. Pretreatment gadolinium-enhanced coronal T1-weighted image (A) shows the enhancing mass in the dome of the liver; the corresponding functional transfer constant (K^{trans}) map (B) was obtained after postprocessing. Two weeks after sunitinib therapy, the tumor demonstrated a reduction in enhancement (C) and a 96% drop in K^{trans} (D).

Summary

Perfusion imaging is finding increasing applications as a functional imaging tool in the field of oncology. Despite their shortcomings, perfusion CT and MRI have the potential to play a crucial role in the management of patients with cancer,

particularly as a biomarker for monitoring response to newer targeted therapies, such as antiangiogenic drugs. However, more collaborative research and robust validation are imperative before this innovative technique can find its utility in routine clinical practice.

Complications

The acquisition of tissue from lesions that are neither visually apparent nor palpable has evolved from being performed in the operating room by surgeons to being performed percutaneously by radiologists with image guidance. Image-guided percutaneous biopsies have also evolved from being reserved for large and superficial lesions to include small, deep, and precariously positioned lesions. With these changes has come a trend toward more outpatient procedures, fewer complications, and lower cost. Because radiologists are willing to perform biopsy of more challenging lesions, there has also been a trend toward imaging techniques with real-time guidance, such as ultrasonography (US) or computed tomography (CT) fluoroscopy. In the past, the success of image-guided biopsies has depended not only on the expertise of the radiologist but also on that of the cytopathologist. Whereas a proficient cytopathologist is extremely advantageous, often enabling a sample consisting of only a minimal amount of tissue to be diagnostic, the increased use of core or cutting biopsy needles has diminished the overall impact of that contribution.¹

The role of image-guided percutaneous biopsy is mainly to diagnose or to exclude the presence of malignant disease, to stage patients with a known malignant neoplasm, to monitor the response to tumor therapy, to confirm or to exclude recurrent tumor, and to differentiate whether nodal enlargement is due to tumor or infection. Furthermore, biopsy techniques can

be used to diagnose nonmalignant medical diseases in the liver and kidneys. For these “medical”-type biopsies, larger bore needles are generally required to obtain specimens for histology.

The challenge facing radiologists is to provide a biopsy service whereby adequate tissue can be readily obtained from almost any lesion in the abdomen and pelvis, on almost any patient, with near real-time needle-tip visualization during both placement and sampling. This has numerous implications related to the coagulation status and condition of the patient, the choice of imaging modality, the choice of type and gauge of needles, and the transgression of normal structures. This chapter discusses the details of these techniques in a systematic fashion including the preprocedural evaluation, choice of modality for image guidance, choice of needles, biopsy planning, specific organ-related details, and complications.

Preprocedure Evaluation

A complete preprocedure evaluation is an important component of an efficient and effective biopsy service. This evaluation should consist of reviewing prior diagnostic imaging studies, obtaining a bleeding history and appropriate laboratory studies, and obtaining written informed consent. We have found that incorporating physician extenders into the procedural approval process helps ensure that biopsies are performed as efficiently and safely as possible. Integration of physician assistants, nurse practitioners, and nurse coordinators allows the radiologist to focus on the procedure, improving throughput. Furthermore, many of these patient encounters, whether they are performed on an inpatient or elective outpatient basis, can be coded and billed as a specialty consultation, allowing the radiology group to be reimbursed appropriately.

Review of prior diagnostic imaging studies will confirm the presence of a lesion suitable for biopsy and help in planning of a specific approach, choice of the appropriate guidance modality, and characterization of the lesion to provide the pathologist with an appropriate differential diagnosis. The importance of reviewing prior imaging studies cannot be overstated. For example, a radiologist may be asked to biopsy a lesion that, on review, proves to be a benign hemangioma or cyst.

The appropriate laboratory investigation of the patient before a biopsy remains the subject of debate. No single published guideline is widely accepted or used. This lack of consensus stems from the fact that no prospective evaluation of a large number of patients has been performed in which various factors, including patient history, specific type of procedure, and laboratory tests, have been compared with outcome.^{2,3}

Silverman and colleagues² proposed a strategy for screening laboratory tests for abdominal interventional procedures based primarily on the bleeding risk of the procedure and screening

of patients for bleeding tendencies. Since the work by Silverman and coworkers, consensus guidelines have been published by the Society of Interventional Radiology^{4,5} (Table 71-1). The recommendations are based on available literature and consensus expert opinion but, admittedly, lack high-level evidence. As a result, the recommendations can conflict with other publications. For example, in a review by O'Connor and associates,⁶ the international normalized ratio (INR) and platelet transfusion threshold for percutaneous liver biopsy were 2.0 or lower and 25,000/mL or higher, respectively, whereas, the Society of Interventional Radiology guidelines^{4,5} recommend an INR and platelet transfusion threshold of 1.5 or lower and 50,000/mL or higher, respectively. The lack of high-level data contributes to the nonuniform pattern regarding management of hemostatic defects. It is likely that individual practitioners will tailor their guidelines to local expertise and patient comorbidities.

A patient's bleeding risk is also influenced by medication use, with emphasis on anticoagulant and antiplatelet agents. Anticoagulant medications have traditionally included warfarin and unfractionated heparin. Newer anticoagulants include low-molecular-weight heparin (e.g., enoxaparin), indirect factor Xa inhibitors (e.g., fondaparinux, idraparinux, idrabiotaparinux), direct Xa inhibitors (e.g., rivaroxaban and apixaban), and direct thrombin inhibitors (e.g., lepirudin, argatroban, bivalirudin, dabigatran). The lack of objective data evaluating the periprocedural management of patients receiving anticoagulant or antiplatelet agents⁷⁻⁹ makes the proposal of general recommendations for the interventionalist difficult. The American College of Chest Physicians has proposed stratifying patients on the basis of risk for perioperative thromboembolism.¹⁰ Patients are classified as being at low, moderate, or high risk for thromboembolic events (Table 71-2). By use of this classification scheme,

TABLE 71-1 Hematologic and Coagulation Parameters for Interventions

Category	1	2	3
Procedure	Low bleeding risk, easily detected and controllable (e.g., paracentesis, superficial aspiration, and biopsy)	Moderate bleeding risk (e.g., intra-abdominal or retroperitoneal biopsy)	Significant bleeding risk, difficult to detect or to control (e.g., renal biopsy)
Tests	INR: recommended only for patients receiving warfarin or with known or suspected liver disease aPTT: recommended only for patients receiving unfractionated heparin	INR: recommended aPTT: recommended only for patients receiving unfractionated heparin	INR: recommended aPTT: recommended
	Platelet count: not routinely recommended	Platelet count: not routinely recommended	Platelet count: recommended
	Hematocrit: not routinely recommended	Hematocrit: not routinely recommended	Hematocrit: recommended
Management	INR: correct to ≤ 2.0 Platelets: recommend transfusion $\leq 50,000/\mu\text{L}$ aPTT: no consensus Hematocrit: no consensus	INR: correct to ≤ 1.5 Platelets: recommend transfusion $\leq 50,000/\mu\text{L}$ aPTT: no consensus Hematocrit: no consensus	INR: correct to ≤ 1.5 Platelets: recommend transfusion $\leq 50,000/\mu\text{L}$ aPTT: correct so that value is ≤ 1.5 times control Hematocrit: no consensus

aPTT, Activated partial thromboplastin time; INR, international normalized ratio.

Modified from Society of Interventional Radiology consensus guidelines for periprocedural management of coagulation status and hemostasis risk in percutaneous image-guided interventions.^{4,5}

TABLE 71-2 Risk Stratification for Perioperative Thromboembolism

Risk Stratum	INDICATION FOR ANTICOAGULATION		
	Mechanical Heart Valve	Atrial Fibrillation	VTE
High (>10% annual risk of thromboembolism)	Any mitral valve prosthesis Any caged-ball or tilting-disk aortic valve prosthesis Recent (within 6 months) stroke or TIA	CHADS ₂ score of 5-6 Recent (within 3 months) stroke or TIA Rheumatic valvular heart disease	Recent (within 3 months) VTE Severe thrombophilia (e.g., deficiency of protein C or S or antithrombin, antiphospholipid antibodies)
Moderate (5%-10% annual risk of thromboembolism)	Bileaflet aortic valve prosthesis and one or more of the following risk factors: atrial fibrillation, prior stroke or TIA, hypertension, diabetes, congestive heart failure, age >75 years	CHADS ₂ score of 3-4	VTE within 3-12 months No severe thrombophilia (e.g., heterozygous factor V Leiden or prothrombin gene mutation) Recurrent VTE Active cancer (treated within 6 months or palliative)
Low (<5% annual risk of thromboembolism)	Bileaflet aortic valve prosthesis without atrial fibrillation and no other risk factors for stroke	CHADS ₂ score of 0-2 (assuming no history of stroke or TIA)	VTE > 12 months previous and no other risk factors

CHADS₂: 1 point is allotted for congestive heart failure, hypertension, age older than 75 years, and diabetes; 2 points are allotted for stroke or transient ischemic attack.

TIA, Transient ischemic attack; VTE, venous thromboembolism.

Modified from the 2012 American Association of Chest Physicians guidelines for perioperative management of antithrombotic therapy.¹⁰

TABLE
71-3

Management of Commonly Used Anticoagulant and Antiplatelet Agents

Medications	Category 1 Procedure (Low Bleeding Risk)	Category 2 Procedure (Moderate Bleeding Risk)	Category 3 Procedure (Significant Bleeding Risk)
Warfarin	Withhold 3-5 days (INR \leq 2.0)	Withhold 5 days (INR \leq 1.5)	Withhold 5 days (INR \leq 1.5)
Heparin (unfractionated)	No consensus	No consensus	Withhold 2-4 hours before procedure
Low-molecular-weight heparin (therapeutic dose)	Withhold 1 dose or 12 hours before procedure	Withhold 1 dose or 12 hours before procedure	Withhold 2 doses or 24 hours before procedure
Aspirin*	Do not withhold	Do not withhold	Withhold 5 days before procedure
Clopidogrel*	Withhold 0-5 days before procedure	Withhold days before procedure	Withhold for 5 days before procedure

INR, International normalized ratio.

*Patients unable to safely discontinue medications for any number of medical reasons, including but not limited to recent coronary or cerebrovascular stents, should be afforded a degree of variance from these guidelines.

Modified from Society of Interventional Radiology consensus guidelines for periprocedural management of coagulation status and hemostasis risk in percutaneous image-guided interventions.^{4,5}

patients with the highest thromboembolic risk and scheduled to undergo a procedure with a high hemorrhagic risk (e.g., renal biopsy) stand to benefit the most from interruption of anticoagulation and bridging with an anticoagulant with a short half-life (e.g., enoxaparin). In observational studies, this regimen was associated with a 1% to 2% incidence of thromboembolic events in the high-risk group.^{11,12} There is a paucity of evidence to guide the use of bridging anticoagulation for moderate- and low-risk categories.

If anticoagulation can be withheld, it is frequently helpful to allow a time lapse of five half-lives, which corresponds to a residual drug activity of 3% from the initial dose. Whereas making decisions based on the half-life of a drug is reasonable, clearance can be affected by drug-drug interactions, differences in metabolism, and genetic influences.⁵ If a procedure requires more urgency, an elevated INR may be reversed immediately by administering fresh frozen plasma. Alternatively, vitamin K can be used to reverse the effects of warfarin.¹³ An elevation of partial thromboplastin time induced by heparin may be reversed with protamine, a heparin antagonist. Low-molecular-weight heparin (i.e., enoxaparin) has a half-life of 4.5 to 7 hours, based on anti-Xa activity. In general, most percutaneous interventions in the abdomen and pelvis can be performed after withholding of the therapeutic dose on the morning of the procedure.

Similar to anticoagulants, antiplatelet agents can also increase a patient's hemorrhagic risk during surgery.^{14,15} Platelet inhibitors include aspirin, thienopyridines (clopidogrel, prasugrel, ticlopidine), and glycoprotein IIb/IIIa inhibitors (e.g., abciximab, eptifibatide, tirofiban). Appropriate management of antiplatelet agents is determined by the indication. Most common indications include secondary prevention of ischemic cardiac events, post-coronary stenting, and secondary prevention of cerebrovascular events.¹⁶ Stopping of these agents should be considered carefully. At our institution, it is common to consult the treating cardiologist before cessation to better understand the risks associated with stopping of the medication against the hemorrhagic risk of the procedure. If a cardiac event occurred within 1 year and the patient is taking aspirin or clopidogrel, we generally perform the biopsy without stopping the medication but inform the patient of the increased hemorrhagic risk. Aspirin, clopidogrel, prasugrel, and ticlopidine irreversibly inhibit platelet function, making the half-life of the drug irrelevant.¹⁷ For each day that one of these agents is withheld,

approximately 10% to 14% of the normal platelet function is restored, taking 7 to 10 days for the entire platelet pool to be replenished.^{18,19} On the other hand, dipyridamole, cilostazol, and nonsteroidal anti-inflammatory drugs reversibly inhibit platelet function, and their effects are dependent on the elimination half-life.¹⁰ The Society of Interventional Radiology has published consensus guidelines on appropriate management of anticoagulant and antiplatelet medications (Table 71-3).

Written informed consent should be obtained from each patient. The biopsy procedure should be described to the patient thoughtfully in layman's terms. Patients should be informed of the risk of bleeding and infection and that biopsy of upper abdominal lesions may result in a pneumothorax and possibly chest tube placement. Patients should be informed that multiple needle passes may be required, the specimen may not be diagnostic, and additional work-up may be necessary. Patients with lesions near bowel are at risk of bowel injury and abscess, although this complication, surprisingly, has only rarely been reported. The preprocedure visit is also an excellent opportunity to assess various factors, such as the patient's airway, ability to lie in the desired position, and level of anxiety. All these variables play a role in deciding the level of sedation (i.e., moderate sedation, often administered by the radiologist, or a higher level of sedation requiring an anesthesiologist). A detailed home care instruction form is reviewed with each patient before the biopsy that explains which symptoms are to be expected after the biopsy and which symptoms raise the question of a complication. This form provides a list of contact telephone numbers in case a complication occurs.

Choice of Modality for Image Guidance

Numerous modalities are available for performing image-guided percutaneous biopsies: fluoroscopy, US, CT (with or without fluoroscopic capability), and magnetic resonance imaging (MRI). Each of these techniques has strengths and weaknesses as well as specific indications, and they are discussed next.

FLUOROSCOPY

Fluoroscopy is used sparingly within the abdomen and pelvis and is reserved for lesions that are large, superficial, or calcified.

Fluoroscopy can also be used on occasion to perform a biopsy of obstructing lesions, such as a cholangiocarcinoma located adjacent to or surrounding a surgically or endoscopically placed stent. US, however, can also accomplish this task. Preliminary cross-sectional imaging with CT, US, or MRI is important to determine which intervening structures the needle may transgress en route to the lesion.

ULTRASONOGRAPHY

The use of US for image-guided biopsies is generally preferred for its accuracy, safety, decreased costs, decreased procedure time, widespread availability, multiplanar capabilities, and flexible patient positioning. US has the major advantage of direct real-time visualization of the needle tip during both placement and sampling.²⁰ This advantage not only aids in avoiding blood vessels but also helps ensure that sampling is restricted to the lesion. Furthermore, compression with the US transducer is a major advantage in that it not only reduces the distance between the skin surface and the lesion but also displaces bowel and other structures. Color Doppler US should be used to assess lesion vascularity and to avoid transgression of nearby vascular structures.

Careful sampling of the lesion alone is particularly important in certain scenarios, such as in differentiating a hepatocellular adenoma from focal nodular hyperplasia. The conspicuous absence of bile duct epithelium in adenomas is the key to differentiating these two hepatocyte-containing lesions. Therefore, if one is performing a biopsy of an adenoma and the needle tip ventures beyond the margins of the lesion into normal hepatic parenchyma, the bile duct constituents that are aspirated may cause the cytopathologist to inadvertently diagnose the lesion as a focal nodular hyperplasia. This could lead to an error in diagnosis, which is important to avoid; many adenomas are surgically resected because they are considered to be premalignant and can undergo spontaneous hemorrhage.

The disadvantages of US include the obscuration of some lesions by intervening lung, bone, or bowel. An angled approach or transducer compression can be used to improve visualization. Needle-tip visualization can be difficult with modern transducers that are narrowly collimated. This difficulty can be reduced by using an attached needle guide. Visualization can also be poor in larger patients, in whom sonographic tissue penetration is poor. Finally, ultrasound of solid abdominal viscera is limited in the setting of tissue heterogeneity (e.g., liver cirrhosis). Contrast-enhanced CT and MRI are excellent tools to detect lesions within solid organs.^{21,22} Image fusion of contrast-enhanced CT or MRI examinations with US allows ultrasound-guided biopsies to be performed with high success²³; however, the technique requires additional hardware for needle tracking and software for coregistration.

The two main techniques of US-guided biopsies are the freehand technique and the attached needle guide technique.^{8,9} The freehand technique has the advantages of allowing many more degrees of freedom and the ability to separate the needle and the transducer, an approach that often results in better needle visualization. The main disadvantage is the steep learning curve because needle-tip visualization can be difficult and time-consuming. The attached needle guide has the advantages of a shallow learning curve with easier and quicker needle-tip visualization. Disadvantages include a significant reduction in the degrees of freedom and the modest cost of the apparatus.

COMPUTED TOMOGRAPHY

CT is widely used for image guidance in the United States primarily because of equipment availability and user preference. CT has the advantages of very high spatial resolution and lack of imaging “blind spots.” Furthermore, the depiction of intervening structures is superb. Disadvantages include the exposure to ionizing radiation, the lack of direct real-time needle-tip visualization, the difficulty encountered in the biopsy of moving lesions, and the high cost. Although CT is limited to the axial plane, the ability to angle the gantry up to 30 degrees allows some limited flexibility in needle placement, particularly in the cephalocaudal direction. An alternative to angling the gantry is to use the triangulation method, in which three points composed of the lesion (A), the skin overlying the lesion (B), and a point either cranial or caudal to the lesion (C) are selected in the same parasagittal plane. The position of C should be selected such that a line formed between A and C does not transgress any critical structures (see later, routes to avoid). These three points form a right triangle, and by trigonometry, the length and angle of insertion can be calculated (Fig. 71-1).²⁴

CT fluoroscopy is capable of providing six to eight lower resolution and low-milliamperage images and near real-time needle-tip visualization.¹⁰ This technique reduces the time advantages of US considerably and improves the targeting of moving lesions. It is particularly useful for procedures involving deep structures, such as retroperitoneal masses, or for procedures involving organs prone to respiratory motion, such as the liver. CT fluoroscopy may use a quick check technique, which is analogous to conventional CT. This technique uses single-section CT fluoroscopic images to check needle location and to confirm appropriate alignment. Continuous CT fluoroscopic images may be obtained in the region of the needle when the needle tip is difficult to localize, such as when it is in an oblique or a transverse plane. This technique is analogous to conventional CT, except reconstruction times are faster and

Figure 71-1 An 87-year-old man with melanoma. Parasagittal reformation of an intravenous and oral contrast-enhanced CT of the upper abdomen reveals a right adrenal mass. Because biopsy of the lesion through an axial approach would have transgressed lung, the triangulation method was used. Three points are selected: A, the lesion; B, the skin overlying the lesion; and C, a point either cranial or caudal to the lesion. The position of C was selected such that a line formed between A and C did not transgress any critical structures. These three points form a right triangle, and by trigonometry, the needle length distance and angle of insertion were appropriately calculated. Fine-needle aspiration revealed metastatic melanoma.

the radiologist may manually position the table. Continuous fluoroscopy denotes the use of continuous fluoroscopic exposure during needle advancement or manipulation. It is wise to use forceps as a needle holder to prevent primary beam irradiation of the radiologist's hands.

Radiation doses to the patient and radiologist are higher in CT fluoroscopy than in conventional CT; however, observed doses have fallen with the trend toward the quick check technique and modulation of two scanner parameters, which are usually readily displayed: CT dose index and dose-length product. These parameters can be lowered by modifying the longitudinal scan length, number of scans, and tube current-exposure time product (milliamperage \times second [mAs]).²⁵

Solid masses, which are isodense to surrounding organ parenchyma, are difficult to biopsy. Intravenous contrast material may be administered to increase lesion conspicuity. We recommend administering intravenous contrast material after placement of the guide needle or biopsy needle near the lesion, based on anatomic landmarks.

MAGNETIC FIELD-BASED ELECTRONIC GUIDANCE SYSTEM

Electromagnetic navigation systems have been developed to aid in near real-time needle tracking. The technology uses real-time positioning information obtained when a probe containing embedded sensors is moved within a magnetic field during CT- or US-guided procedures.^{26,27} The postprocessed images allow the operator to quickly assess the needle trajectory before entering the patient's skin. As the needle is advanced down to the lesion, the screen displays the real-time needle position by overlaying it on a preprocedural CT or US set of images. This technology helps facilitate out-of-plane biopsy approaches.

MAGNETIC RESONANCE IMAGING

MRI has been used sparingly for guiding percutaneous biopsies, although the roadblocks to use of this modality are diminishing. The advantages of MRI include high spatial resolution, very high inherent tissue contrast, lack of ionizing radiation, real-time capability, and virtually unlimited multiplanar imaging planes, which facilitates needle placement for lesions not readily accessible with a traditional axial approach (Fig. 71-2).

Disadvantages include the requirement for MR-compatible supplies and monitoring equipment, the considerable time commitment, and the high cost. Many of these disadvantages, however, are significantly reduced or eliminated with the open or dedicated interventional units, which allow placement of the needle while the patient is in the bore of the magnet and use fast imaging sequences that provide near real-time guidance.²⁸ The use of lower field strength in an open system decreases the signal-to-noise ratio and results in longer acquisition times but may still be sufficient for lesion visualization.²⁹ The high inherent tissue contrast attainable on noncontrast MRI can be a major advantage; in most practices, this modality is used selectively in patients with lesions that are not well seen on US and CT. This imaging scenario, however, is infrequent in the abdomen.

Choice of Needles

In choosing a needle for image-guided biopsy, the first issue to address is what technique will be used to acquire the sample. A single-needle technique uses a new needle for each pass. This is limited by the necessity of imaging guidance for each pass, resulting in long procedure times, need to traverse structures with each pass, increase in the risk of complications, and increased radiation exposure when CT guidance is used.³⁰ In the tandem technique, a small-caliber needle is first used to localize the lesion with image guidance. A larger caliber biopsy needle is then advanced parallel to the localizing needle without imaging guidance. This technique is limited by multiple organ punctures and imprecise needle-tip localization.³⁰ At our institution, most operators use a coaxial technique, during which a guide needle is advanced down to the lesion under imaging guidance. Biopsy needles are then advanced coaxially through the guide needle. The drawbacks include having to use a larger caliber guide needle to accommodate the biopsy needle and that subsequent passes may follow the same path and yield little diagnostic tissue.^{30,31}

Guide needles are available in a wide range of size, length, and tip configuration. In general, the needles used for biopsies in the abdomen and pelvis range in size from 16- to 19-gauge and 5 to 20 cm in length. The tips of the guide needles may have an angled bevel or a stylet with a sharp point. A drawback of the beveled needles is that they may deflect away from the

Figure 71-2 MRI of a 76-year-old woman with ampullary carcinoma. **A.** Axial T2-weighted MRI demonstrates a 1.2-cm T2 hyperintense lesion in the hepatic dome (arrow). **B.** Coronal MRI demonstrates the biopsy needle within the hepatic dome lesion (arrowhead). Given its multiplanar capabilities, MRI facilitates biopsy of lesions that would be difficult to target by conventional axial approaches. Fine-needle aspiration revealed hepatocytes with focal chronic inflammatory cells.

Figure 71-3 Biopsy needles.

intended target as they pass through tissue interfaces, which renders accurate needle placement somewhat more difficult. Needles with a pointed stylet tend to track along a straight line. The Hawkins-Akins needle (Cook Medical, Inc., Bloomington, Ind) also contains an interchangeable blunt stylet, which reduces the risk of injury to bowel, nerves, and blood vessels.³²⁻³⁴

Many biopsy needles are available. These can be broadly grouped into aspirating and cutting needles (Fig. 71-3). The aspirating needles are usually 20- to 25-gauge and are designed to yield individual cells or small clumps of cells that can be spread into a single cell layer for cytopathologic analysis. The “skinny” 22- or 25-gauge needle, although in widespread use, is very flexible and particularly susceptible to bending and deflection. At times, however, the purposeful bending of such a thin-gauge needle can aid in targeting lesions that would be difficult to access otherwise. A curved needle placed coaxially through a straight needle is advantageous because it can compensate for inaccurate guide needle placement and can also sample different regions of a lesion without having to manipulate the outer needle.³⁵ If a curved needle is used without a guide needle, care should be taken in inserting the needle as rotation of the needle may result in a lacerating effect.³⁶

Many radiologists attach a syringe and tube to the needle to apply suction during the actual biopsy. We have abandoned the use of this suction method in favor of simply removing the stylet and relying on natural capillary forces and mechanical agitation to draw tissue into the needle.³⁷ The main advantage of the nonsuction technique is that the specimens are usually free of blood. Fibrin clots form quickly within bloody aspirates, rendering them difficult to smear onto a glass slide. Also, the presence of abundant erythrocytes obscures cellular detail.

The cutting needles, usually 14- to 20-gauge, are designed to obtain a core of tissue suitable for histologic analysis. Most radiologists have adopted the use of automated cutting needles.^{38,39} These automated needles have an inner slotted stylet for the specimen and an outer cutting stylet. They consistently provide an excellent core of tissue. Manufacturers have designed single-use automated or semiautomated cutting needles that are so lightweight they will maintain their position during the movement of patients in and out of the CT gantry. Cutting needles with a short, long, or adjustable excursion are available. Many of these needles lend themselves to a coaxial technique, permitting several biopsy samples to be obtained from a single skin and organ puncture. In a blinded evaluation of 20 automated cutting biopsy devices, the best overall performance was obtained with 18-gauge needles with at least a 2-cm excursion.³⁸

It has been suggested that radiologists should use the smallest gauge needle possible in performing biopsy procedures. Researchers have explored the effect of needle gauge on organ bleeding in the pig model.^{40,41} This work shows that in general, larger needles produce greater bleeding. The research also shows that large needles yield greater amounts of tissue. To the extent that each needle pass carries risk, the maximum tissue yield can be obtained at minimum risk by performing fewer passes with a larger needle. There are two caveats to consider. First, cytopathologists prefer to analyze a thin layer of single cells or clumps of cells. Samples obtained from thin needles (i.e., 20- to 25-gauge) may be easier to smear into a single cell layer than samples from larger needles (14- or 18-gauge). Second, use of cutting needles is riskier than use of aspirating needles. If the knifelike blade of the cutting needle encounters an artery or a vein, the vessel will be lacerated and bleed. In contrast, aspirating needles tend to displace rather than to cut tissue.

MRI is used to guide tissue biopsies particularly in the central nervous system and breast.^{29,42} Dedicated MR-specific needles are now available,⁴³ although the selection of biopsy needles and sizes is considerably more limited than with the ferromagnetic needles traditionally used in US and CT cases. These nonferromagnetic needles are readily visualized as a signal void and are safe to use in the magnetic field. Use of a ferromagnetic needle, on the other hand, can cause considerable image distortion that may obscure the lesion of interest and hinder precise needle localization. In addition, they may be torqued or deflected in the magnetic field, raising questions about their safety.

It is vital to coordinate needle selection with the pathologist who will interpret the case. If the pathologist is skilled in cytopathology, small-bore (20- to 25-gauge) aspirating needles are recommended. If the pathologist prefers samples for histologic analysis, larger bore cutting needles are appropriate. Some groups perform a cytopathologic touch preparation for samples obtained with core needles. This technique allows a rapid preliminary diagnosis and preserves the core material for permanent fixation and sectioning.⁴⁴

Biopsy Planning

In planning the approach to a lesion, one must decide not only on the needle type but also on the needle route, the guidance modality, and the most efficient and comfortable patient position. The choice of needle route to a lesion will be based on the presence of intervening structures. Because needle passage through an organ creates both an entrance and an exit wound, this is indeed an important consideration. Whereas some organs tolerate this type of transgression, others do not, and henceforth these are referred to as acceptable and unacceptable transgressions.

ACCEPTABLE ROUTES

Organs through which needle transgression is acceptable include the liver, lungs, and gastrointestinal tract. The liver, because of its size and solid nature, provides not only a window for sonographic imaging of the upper abdomen but also an access route for the biopsy of deep masses. This includes masses involving the gallbladder, pancreatic head and body, porta hepatitis, adrenal gland (Fig. 71-4), and, on occasion, right kidney. Needles ranging up to 14-gauge in caliber and of all

types are usually well tolerated as long as blood vessels are avoided.

The lungs can usually be avoided when US is used for guidance because an off-axis approach allows one to angle the transducer cranially to avoid the pleural space. Even when the pleural space is violated, the lung parenchyma itself is often spared, reducing the risk of pneumothorax considerably. When CT is used to biopsy subdiaphragmatic lesions, lung transgression is sometimes unavoidable, although this is usually well tolerated when needles of 20-gauge or smaller are used, and, typically, chest tube placement is unnecessary.

The gastrointestinal tract can also tolerate needle transgression. The stomach, being thick walled, can tolerate puncture with needles up to 18-gauge or even larger. Transgression of the

stomach, however, can be challenging because the wall is resilient and the needle may induce a peristaltic contraction.

Some interventionalists hesitate to transgress the small bowel because of its thin wall and fear of perforation and abscess formation. However, in our experience using 20-gauge needles, such transgressions are well tolerated. Newer 20-gauge automated cutting needles are particularly useful for the biopsy of deep lesions or lymph nodes because transenteric excursion is virtually unavoidable. Transducer compression effectively reduces lesion depth by displacing or flattening bowel and adipose tissue (Fig. 71-5).^{45,46}

Transcolonic needle excursion is somewhat more controversial because of the fear of bacterial contamination within the peritoneal cavity. However, as with the small bowel, the colon is undoubtedly violated at times during US-guided biopsies using transducer compression. Passing a needle through stool-filled bowel, which may be unavoidable with CT, may be another issue, at least empirically (Fig. 71-6). In this scenario, it may be prudent to administer antibiotics (e.g. gentamicin 80 mg intramuscularly within 60 minutes prior to the procedure plus 250 mg ciprofloxacin twice daily orally for 5 days following the procedure). As with the small bowel, whenever colon transgression is anticipated, a needle on the order of 20-gauge or smaller is recommended.

Hydrodissection is a technique in which structures can be safely displaced away from the targeted mass.³⁴ Fluids, such as physiologic sterile saline, can be safely infused to create an artificial space and allow safe passage of a biopsy needle (Fig. 71-7). Hydrodissection generally works well in the retroperitoneum (e.g., to widen the paravertebral space before adrenal biopsy or to displace the ascending colon, descending colon, or second portion of the duodenum).³⁶ In the peritoneum, however, this technique is limited as fluid diffusion within the peritoneal cavity and mesenteric folds becomes difficult to control.⁴⁷

Transgression of vascular structures should be avoided whenever possible. Nevertheless, there is anecdotal evidence to suggest that the aorta is tolerant of needle transgression (Fig. 71-8). Certainly, early interventional experience with translumbar aortography using 16- and 18-gauge needles corroborates this contention.⁴⁸ Additional reports describe transaortic endoscopic US (EUS)-guided fine-needle aspiration of thoracic para-aortic lesions using 22- and 25-gauge needles as safe.^{49,50} Transgression of the inferior vena cava is also feasible, safe, and

Figure 71-4 CT scan of a 66-year-old man with lung carcinoma. Axial noncontrast CT of the upper abdomen reveals an enlarged left adrenal gland (arrow) adjacent to the gastric fundus/proximal gastric body (arrowheads). The left adrenal gland was biopsied with a transhepatic approach. The liver tolerates needle transgression well as long as blood vessels are avoided. Fine-needle aspiration revealed metastatic carcinoma. Of note, the patient was initially scanned in the prone and left lateral decubitus positions in the hope of accessing the lesion posteriorly, but the intervening left kidney prevented this approach.

Figure 71-5 Images of a 57-year-old man with abdominal pain and weight loss. **A.** Axial CT of the upper abdomen with contrast material reveals a rounded fullness in the pancreatic head with subtle hypoattenuation changes (arrow). Note numerous blood vessels anterolateral to the pancreatic head as well as colon and jejunum anteromedially. **B.** Gray-scale ultrasound in the transverse plane reveals a hypoechoic, rounded mass in the region of the pancreatic head (arrowheads). Note that with transducer compression, there has been considerable decrease in the distance from the skin to the mass as well as displacement of intervening bowel. Fine-needle aspiration revealed adenocarcinoma.

Figure 71-6 CT of a 70-year-old woman with abdominal pain and jaundice. The patient underwent preliminary endoscopic retrograde cholangiography (not shown) suggesting a mass involving the distal common bile duct. A plastic biliary stent was inserted. Follow-up noncontrast axial CT scan of the upper abdomen reveals some rounded fullness of the pancreatic head but no obvious mass. Percutaneous biopsy was performed by an anterior transcolonic approach. Because no obvious mass was identified, biopsy samples were taken adjacent to the stent (arrow). Fine-needle aspiration revealed adenocarcinoma. There were no hemorrhagic or infectious complications.

Figure 71-7 CT of a 55-year-old man with confluent adenopathy along the lesser curvature of the stomach (arrows). An 18-gauge Hawkins-Akins needle was advanced into the left paravertebral space, and approximately 30 mL of sterile 0.9% saline was injected to create an artificial space to avoid pulmonary transgression. Fine-needle aspiration biopsy revealed diffuse large B-cell lymphoma. A chest radiograph after the procedure demonstrated no pneumothorax.

well tolerated, as illustrated by studies using CT-guided fine-needle aspiration biopsy of pancreatic and peripancreatic lesions by a posterior transcaval approach.^{51,52} The 18-, 20-, and 22-gauge needles have been used with diagnostic accuracy rates of 86%.⁵¹ At our institution, we advance an 18-gauge Chiba guide needle to the posterior wall of the cava and traverse the cava wall with a 22-gauge aspirating needle and have expanded the use of this technique to other retroperitoneal lesions along the inferior vena cava (Fig. 71-9).

Figure 71-8 CT of a 59-year-old man with back pain and weight loss. Preliminary CT revealed a mass in the pancreatic head and neck encasing the celiac axis and superior mesenteric artery. The mass subsequently underwent biopsy percutaneously in the prone position by a retroperitoneal approach. Initial needle placement revealed aortic violation. The needle was subsequently repositioned into the pancreatic mass, and fine-needle aspiration revealed adenocarcinoma. There were no hemorrhagic complications as a result of aortic transgression.

Figure 71-9 CT of a 76-year-old woman with non-small cell lung carcinoma. Axial CT of the abdomen with contrast material reveals a small lymph node anterior to the inferior vena cava (arrow). An 18-gauge Chiba needle was advanced to the posterior wall of the inferior vena cava, and multiple passes were obtained with a 22-gauge Chiba needle through the inferior vena cava into the lymph node. Cytology revealed metastatic carcinoma. Follow-up CT imaging obtained 15 minutes after biopsy demonstrated no hemorrhage.

ROUTES TO AVOID

A needle path through the pancreas should be absolutely avoided. In a review of percutaneous abdominal sampling by Smith,⁵³ pancreatic biopsy accounted for the second-most number of deaths. Whereas liver biopsy is associated with a higher number of deaths, it is important to consider that the liver is the most commonly sampled abdominal organ. In Smith's review, there were six deaths from pancreatic biopsy, and five were due to pancreatitis. In each of these five cases, no

Figure 71-10 CT of a 48-year-old woman with breast carcinoma. Axial CT of the upper abdomen with contrast material reveals a small nodule in the left adrenal gland. The right adrenal gland was normal. The left adrenal mass underwent biopsy percutaneously through an intercostal and transpancreatic approach. Because normal pancreatic parenchyma is prone to development of pancreatitis when it is transgressed, this technique is not recommended. Fine-needle aspiration revealed no evidence of malignant transformation.

tumor was found. One plausible explanation is that when small lesions are biopsied, the needle probably transgresses normal pancreatic parenchyma, causing enzyme release. Thus, at our institution, it is our policy to avoid needle paths through normal pancreas. This is true for both dedicated pancreatic biopsies and transpancreatic biopsies of deeper lesions (Fig. 71-10).

The following needle paths should be avoided, if possible: through the spleen, adrenals, and kidneys. The spleen is a solid but soft organ that, like the liver, can provide a window to the left upper quadrant, particularly when it is enlarged. However, because of its well-known susceptibility to blunt trauma, there is concern that a splenic biopsy might result in capsular rupture. Transsplenic needle excursion is even more of a concern than splenic biopsies because the capsule is punctured twice. Although complications related to needles and the spleen may be overestimated, we recommend avoiding this organ when needles are placed in the left upper quadrant. The adrenals and kidneys are both associated with hemorrhagic complications of biopsy. Although retroperitoneal hemorrhage after these types of biopsies is often asymptomatic, even when it is substantial, transadrenal or transrenal needle excursion is not recommended.

Specific Organ-Related Techniques

LIVER

The liver is a vascular but relatively resilient organ that tolerates needle placement well, whether for biopsy of a focal liver abnormality, for biopsy of hepatic parenchyma, or to be traversed en route to a deeper lesion. Needles up to 14-gauge are commonly used without difficulty. The liver capsule is richly innervated; therefore, copious infiltration of the capsule with a local anesthetic, such as lidocaine, is necessary to achieve adequate pain control during needle placement. The liver can usually be accessed through a subcostal, subxiphoid, or intercostal approach. The last approach is typically the most difficult, and

Figure 71-11 Ultrasonogram of a 63-year-old man with small cell lung cancer. Gray-scale ultrasound reveals a large hypoechoic mass located deep in the left hepatic lobe (arrow). The mass underwent biopsy percutaneously by a subcostal approach. Fine-needle aspiration revealed metastasis.

Figure 71-12 Ultrasonogram of a 51-year-old man with melanoma. Color ultrasound of the liver following percutaneous needle biopsy of a hypoechoic hepatic mass (long arrows). The needle transgressed approximately 1 cm of normal hepatic parenchyma (short arrows). As the needle (asterisk) was removed from the liver, a tract of blood was evident along the needle path (arrowhead) toward the liver capsule. There was, however, no evidence of subcapsular accumulation of blood, and the track resolved within 30 to 60 seconds.

care should be taken to avoid the intercostal neurovascular bundle, which courses along the inferior margin of each rib. Real-time guidance during needle placement is also helpful for avoidance of major portal and hepatic veins. It is advantageous to interpose a cuff of normal parenchyma (at least 1 cm) between the liver capsule and the margin of a lesion, and this task is more easily accomplished with US by an off-axis approach (Fig. 71-11).

Fine-needle aspiration of focal abnormalities for cytology is typically performed with a 20- to 22-gauge aspirating needle, either a Chiba or Franseen. Medical biopsy of hepatic parenchyma for histology is typically performed with a 20-gauge cutting needle, many of which have a spring-loaded rapid-fire mechanism. Routine assessment of the liver with color Doppler US after withdrawal of one of these larger gauge cutting needles can demonstrate a linear track of blood flowing toward the capsule (Fig. 71-12). These tracks, however, typically resolve

within 2 to 3 minutes without evidence of subcapsular accumulation of blood. Plugging of biopsy tracks with gelatin particles,⁵⁴⁻⁵⁷ gelatin particles and thrombin,⁵⁴ or coils⁵⁸ has been described. Whereas these studies were limited by small numbers of patients, use of these agents appears to be safe and well tolerated.⁵⁴⁻⁵⁸

There has been considerable controversy about the biopsy of hepatic hemangiomas, whether inadvertent or intentional. Because these benign tumors consist of a tangle of thin-walled endothelium-lined blood vessels, there is presumed to be an increased risk for hemorrhagic complications. Several studies have shown, however, that hemangiomas can be biopsied safely with an acceptable complication rate (Fig. 71-13).⁵⁹⁻⁶² This includes the use of 18-gauge aspirating needles and 18-gauge cutting needles. These studies have also emphasized the importance of interposing a cuff of normal hepatic parenchyma between the capsule and the margin of the lesion. Although these results are encouraging, the number of patients included in each of these studies is relatively small, and it is presumed that a large-scale comparative trial of the biopsy of hemangiomas and metastases would reveal a slightly higher complication rate for the biopsy of hemangiomas. Whereas the noninvasive work-up of these common and, in most cases, inconsequential lesions cannot be overemphasized, it is comforting to know that if a hemangioma is biopsied, whether inadvertently or because of nonclassic imaging features, the complication rate is low.⁵⁹

Another issue is the safety of performing a liver biopsy in the presence of ascites. It is presumed that direct contact with the diaphragm or abdominal wall functions to tamponade the capsular injury, thereby preventing significant subcapsular or intraperitoneal hemorrhage. Therefore, when the capsule is in contact with a layer of fluid, the risk of hemorrhagic complications is increased, particularly if patients have a tenuous coagulation status (Fig. 71-14). Two studies in particular have addressed the issue of ascites in patients with cirrhosis.^{63,64} In both reports, the complication rate was low, and when

complication rates were compared between those with ascites and those without ascites, there was no statistically significant difference.

Hepatocellular carcinoma is a locally invasive tumor that often infiltrates and obstructs portal veins, hepatic veins, and even bile ducts. The presence of underlying cirrhosis often excludes a patient from hepatic tumor resection, either because of inadequate residual function or because hepatomas in these patients are typically more aggressive. However, patients with little or no parenchymal dysfunction may be candidates for resection. In these patients, it is imperative to determine if portal or hepatic venous thrombosis is bland or malignant. There are noninvasive means of making this determination, such as enhancement during the hepatic arterial dominant phase of a dynamic bolus CT with iodinated contrast material or MRI with a gadolinium chelate. However, these signs of unresectability are not often present. Biopsy of the intraluminal mass may be requested both to diagnose and to stage this malignant neoplasm. It is useful to use a guidance technique with real-time capability, in biopsy of an intraluminal mass, to ensure that the needle tip does not venture beyond the wall of the vein into an adjacent parenchymal tumor deposit.⁶⁵ US-guided biopsy of portal vein thrombus is safe, accurate, and well tolerated.⁶⁵⁻⁶⁷

In addition to biopsy of focal hepatic masses, US is used to guide random liver biopsies in medical liver disease, such as hepatitis or hemochromatosis. For diffuse liver disease, most hepatopathologists are satisfied with a specimen containing at least six to eight portal triads.⁶⁸ Biopsy is considered the “gold standard” for assessment and grading of liver fibrosis. However, the accuracy of histologic assessment has been challenged because of the nonuniform pattern of liver fibrosis.⁶⁹ For this reason, techniques using US and magnetic resonance elastography have been developed.

Figure 71-13 CT of a 61-year-old woman with vague right upper quadrant pain. Axial noncontrast CT of the upper abdomen reveals a large hypoattenuating mass occupying most of the right hepatic lobe. A central hypoattenuating scar is noted within the mass. Although the mass is large and easily approached through an intercostal space, it underwent biopsy anteriorly, for a cuff of normal hepatic parenchyma to be interposed between the capsule and the mass. Fine-needle aspiration revealed a hemangioma.

Figure 71-14 Ultrasonography of a 42-year-old man with cirrhosis and portal hypertension. Gray-scale ultrasound of the liver in the longitudinal plane revealed a small, shrunken liver with heterogeneous echotexture consistent with cirrhosis. There is also a considerable amount of perihepatic ascites and a 2-cm hypoechoic nodule in the right hepatic lobe anteriorly (arrow). The mass underwent biopsy with ultrasound guidance by an intercostal space through the ascites. Fine-needle aspiration revealed hepatocellular carcinoma. There were no hemorrhagic complications.

ADRENAL GLANDS

The possibility of malignant disease is the primary concern when adrenal masses are discovered. In a study by Young,⁷⁰ incidental adrenal masses were detected in 2005 patients; adrenal cortical carcinoma was diagnosed in 4.7% and metastatic disease in 2.5%. For patients with a history of malignant disease, however, metastatic disease accounts for nearly half of the causes.⁷¹ The role of fine-needle aspiration biopsy is to delineate adrenal and nonadrenal tissue.⁷² Many routes have been used with success. Whereas an anterior approach through the liver (for right adrenal biopsy), stomach, and pancreas has also been described,⁷³ this is rarely used. Patients are most often placed in the prone or lateral position, and a guide needle is generally advanced from a posterior approach. Out-of-plane access is used because of interposed, aerated lung. Methods to circumvent puncture of the lung include the triangulation method,²⁴ angling of the CT gantry,⁷⁴ injection of medical-grade carbon dioxide into the pleural space,⁷⁵ and placement of the patient in the ipsilateral decubitus position.⁷⁶ At our institution, we generally place the patient in the ipsilateral decubitus position to immobilize the diaphragm and to minimize lung aeration. In our experience, this results in a direct, non-transpulmonary route for biopsy, reduces the need for out-of-plane approaches, and is as reliable and safe as the prone position.⁷⁶

Technical success of adrenal biopsy ranges from 80% to 95%.^{77,78} Risks include adrenal hematoma, abdominal pain, hematuria, pancreatitis, pneumothorax, adrenal abscess, and needle track seeding.^{70,74,78} The possibility of pheochromocytoma should be excluded with biochemical testing before biopsy as fine-needle aspiration biopsy can result in adrenal hemorrhage and hypertensive crisis.^{79,80}

PANCREAS

The pancreas is a relatively soft, unencapsulated organ located deep in the upper retroperitoneum that is prone to development of inflammation. Acute pancreatitis can occur not only after a needle biopsy but also after blunt trauma or the direct injection of contrast media into the pancreatic duct during endoscopic retrograde cholangiopancreatography.⁸¹ Pancreatic tumors, including both adenocarcinomas and islet

cell tumors, are often difficult to visualize because there may not be a contour abnormality or there is little tissue contrast compared with adjacent nontumorous parenchyma. Furthermore, pancreatic adenocarcinomas are associated with a considerable amount of tissue desmoplasia, which can increase sampling error.¹

Both EUS-guided FNA and percutaneous image-guided FNA are similarly accurate for the diagnosis for exocrine pancreatic cancer when the lesion is more than 3 cm in size. One advantage of EUS-guided sampling is that it can often find small pancreatic or ampullary lesions that are not clearly visible with CT, MRI, or transabdominal US, thus providing a better guide for biopsy.^{82,83} Also, EUS-guided pancreatic biopsy through the duodenum provides a theoretical decreased risk of malignant seeding intraperitoneally or along the needle path. Despite the advantages of EUS-guided pancreatic sampling, there are still occasions when percutaneous pancreatic biopsy is indicated. In general, small-caliber needles, on the order of 20- to 22-gauge, are used to biopsy the pancreas. Although there is concern about development of a fistula to the pancreatic duct with larger caliber needles, 14-, 16-, and 18-gauge cutting needles can be used to safely biopsy large pancreatic masses.⁸⁴ In general, however, 20-gauge cutting needles are preferred in this scenario. Many of the needles used for fine-needle aspiration are designed to be self-aspirating, although it may be advantageous to use suction in performing a biopsy of pancreatic tumors that are desmoplastic.

Biopsy of pancreatic masses is usually performed by an anterior approach, through either the left lobe of the liver or the gastrointestinal tract, typically the stomach or small bowel. Fine-needle aspiration biopsy of lesions in or around the pancreatic head by a transcaecal approach has also been shown to be safe and effective in obtaining diagnostic tissue.^{51,52} Approaching a mass in the head of the pancreas through the right hepatic lobe, duodenum, or gallbladder is generally not recommended. Furthermore, approaching a mass in the tail of the pancreas through the spleen is not recommended.

In our practice, we prefer US for guidance as it is generally easier than with CT to navigate a needle into the lesion without traversing the numerous peripancreatic blood vessels. Furthermore, perivascular tumor encasement can be biopsied directly and can serve both to diagnose and to stage the tumor (Fig. 71-15). With an anterior approach, compression with the US

Figure 71-15 Images of a 64-year-old woman with vague upper abdominal pain and weight loss. **A.** Preliminary axial CT scan with contrast material revealed a pancreatic head mass (arrow). **B.** This mass (arrow) was subsequently biopsied percutaneously under ultrasound guidance by an anterior approach. The needle tip (arrowhead) is placed directly in this soft tissue. Fine-needle aspiration revealed adenocarcinoma. There were no hemorrhagic complications, and real-time guidance prevented transgression of the artery.

transducer not only reduces the depth of needle placement but also displaces many intervening structures, particularly the transverse colon and jejunum. In some cases, a discrete mass may not be appreciated, yet diagnostic tissue can still be obtained by looking for indirect signs, such as abrupt termination of a dilated duct, or taking a biopsy sample adjacent to a biliary stent. The biopsy of peripancreatic lymph nodes or liver nodules in the setting of pancreatic carcinoma is often productive as well, especially for staging.

A concern about pancreatic biopsies is the potential for peritoneal tumor seeding.⁸⁵ This theory, however, is difficult to substantiate because most patients are inoperable and do not have surgical confirmation, and most do not survive long enough for the implants to reach a size detectable with cross-sectional imaging. It is doubtful that the biopsy of pancreatic adenocarcinoma negatively affects outcome.

BOWEL

Biopsies of the digestive tract are almost always performed endoscopically and, when that is not possible, usually open or laparoscopically. However, endoscopic biopsy may be impossible when the lesion or involved bowel segment lies between the ligament of Treitz and the ileocecal valve. In many of these cases, there may be metastases elsewhere that are better suited to endoscopic biopsy. However, when an isolated bowel wall mass is not amenable to endoscopic biopsy, percutaneous sampling is appropriate.⁸⁶⁻⁸⁸ For example, submucosal lesions such as gastrointestinal stromal tumors may not be easily identified endoscopically.

Percutaneous bowel wall biopsy may be performed with either US or CT guidance, depending on the lesion's characteristics and the patient's body habitus. Our group prefers US guidance as compression with the US transducer may displace overlying bowel loops and anchor the targeted bowel segment, which may otherwise be displaced by the biopsy needle. Color Doppler US may also be used to identify and to avoid adjacent mesenteric vessels. In addition, percutaneous bowel wall biopsy can be performed with either fine-needle aspiration or core needles.^{86,89}

Potential complications particular to biopsies of the digestive tract include bowel hematoma, bowel perforation, and peritonitis. Choosing a biopsy route that does not traverse the bowel lumen may minimize the risk of bowel perforation. Even when the bowel lumen is traversed, the risk of perforation remains low. The study of Marco-Doménech and associates⁸⁷ included eight patients whose histologic samples contained mucosa, indicating that the mucosa and lumen were perforated; however, none had an adverse outcome.

LYMPH NODES

Lymph nodes represent the most common site of metastatic disease. With improvements in image guidance and needle design, radiologists are increasingly requested to biopsy lymph nodes to diagnose and to stage a suspected malignant neoplasm or to obtain samples for culture. This increase in the number of requests for lymph node biopsy may be attributed to discovery of normal-sized but hypermetabolic nodes on positron emission tomography.

We have found US guidance to be accurate and safe for biopsy of abdominal and retroperitoneal nodes with a success

rate of 86%, similar to results from other institutions.^{45,46} Real-time needle-tip visualization helps ensure that sampling will be limited to the lesion; samples are far less likely to be contaminated with extraneous tissue or blood and thus may be easier to interpret by the cytopathologist. With real-time visualization, it is also possible to ensure that the needle excursions are short of adjacent critical structures, such as blood vessels and the common bile duct. We have found that lymph node visualization is improved markedly by applying firm pressure with the transducer to compress and to displace overlying fatty tissue and bowel loops, decreasing the necessary depth for sound penetration and length of needle excursion by approximately 50%. For biopsy of lymph nodes, it is vital to review CT scans before the procedure to choose the optimal site and route.

A special consideration is lymphoma, which can be broadly classified into mature B-cell and T-cell neoplasms. At our institution, the majority of both superficial and deep lymphomatous masses are approached with image-guided biopsy. The combination of cytology fine-needle aspiration and flow cytometry to differentiate reactive lymphoid hyperplasia from a mature B-cell lymphoma has a high sensitivity and specificity (ranging from 94% to 100%) to appropriately classify the disease.⁹⁰⁻⁹³ We attempt to collect at least 1 million lymphocytes, which can be quickly quantified with an automated cell counter. Obtaining sufficient material allows the cytopathologists to perform immunophenotyping and additional ancillary studies, such as immunocytochemistry, fluorescence in situ hybridization, and polymerase chain reaction. Hodgkin's lymphoma patients typically present with supradiaphragmatic lymphadenopathy, with inguinal adenopathy seen in a minority of cases. For Hodgkin's lymphoma, we generally perform a concurrent core needle biopsy. Other groups, however, argue that the initial diagnosis of Hodgkin's lymphoma should be made with a surgical specimen as fine-needle aspiration and core needle samples fail to appropriately depict the architecture of the lymph node, which is important for an accurate diagnosis.⁹⁴ Ultimately, consultation with local experts is necessary to ensure that appropriate specimens are obtained at your institution.

SPLEEN

Requests for percutaneous splenic biopsies are uncommon. This relates to the relative infrequency of isolated splenic disease and the perceived risk of hemorrhagic complications in this soft, encapsulated organ. However, in a meta-analysis to determine the diagnostic accuracy and complication rate of percutaneous image biopsy of the spleen, pooled sensitivity and specificity measured 87.0% and 96.4%, respectively.⁹⁵ The pooled complication rate was 1.3% when needles were 18-gauge or smaller, and the most common complication was hemorrhage followed by pain. The advantages of interposing a cuff of normal splenic parenchyma between the capsule and the lesion are controversial (Fig. 71-16). Unless it is large, the spleen is approached through the intercostal space, and at times, pleural transgression is necessary. This is less of a problem with US than with CT because an off-axis or angled approach can be used.

Complications

In general, abdominal biopsies are safe. Minor complications include pain, vasovagal reactions, small hematomas, pneumothorax, bacteremia, and pancreatitis.^{41,96} The most common

Figure 71-16 Images of a 52-year-old man with melanoma. **A.** Axial CT of the upper abdomen with contrast material reveals a 1.5-cm hypoattenuating mass in the spleen. **B.** Gray-scale ultrasound of the spleen in the longitudinal plane reveals a hypoechoic mass located deep in the splenic parenchyma (arrow). By an intercostal approach, the mass underwent biopsy percutaneously with the attached needle guide. Note that the mass is aligned within the parallel dotted lines, which represent the proposed path of the needle when it is advanced through the attached guide. Fine-needle aspiration revealed metastatic melanoma.

minor complication is pain or vasovagal reaction, which occurs in approximately 1% to 5% of patients. Fortunately, less than 1% of patients will have a hematoma large enough to require a transfusion. An additional minor complication of biopsies in the upper abdomen is pneumothorax.⁹⁶ Whereas there is a theoretical risk of pneumothorax when the potential space of the pleura is transgressed, pneumothorax is extremely rare unless the aerated pulmonary parenchyma is transgressed as well. It is our impression that the risk of pneumothorax is decreased with the use of US compared with CT guidance. Pancreatitis after biopsy is a well-described complication. Paradoxically, pancreatitis tends to occur only when the normal pancreatic parenchyma is transgressed; biopsies of the diseased pancreas (chronic pancreatitis or cancer) are usually well tolerated and rarely result in pancreatitis. Although pancreatitis is often considered a minor complication, some patients with biopsy-related pancreatitis may be critically ill, requiring prolonged hospitalization.

When the bowel is transgressed, there is a risk of microperforation and subsequent abscess formation. Theoretically, the risk of peritonitis is increased when the colon is transgressed compared with when the small bowel or stomach is transgressed because of the relatively sterile contents of the last two structures. With the use of US guidance and abdominal wall compression, it is often not possible to differentiate collapsed loops of small bowel from mesenteric fatty tissues. There is no doubt that needle transgression of bowel occurs more frequently with

US guidance than with CT guidance. Despite the increased use of US for guidance at our institution, we have not detected an increase in abscess formation or peritonitis. In support of this observation, Petit and associates⁹⁷ found that in pigs, transgression of the large and small bowel with 8F catheters was not associated with peritonitis or abscess formation. Care should be exercised, however, when there is transgression of colon for biopsy of a fluid-containing structure as the sample and lesion can become contaminated.³⁶

Fortunately, serious complications are rare.^{53,97-99} The mortality rate from an image-guided percutaneous abdominal biopsy is widely considered to be 0.1%. However, a retrospective review of complications by Smith⁵³ suggested that the mortality rate from abdominal fine-needle aspirations may in fact be as low as 0.006% to 0.031%. The majority of reported deaths from biopsies are from hemorrhage after a liver biopsy. Interestingly, most of the reported deaths from liver biopsies occurred with use of skinny needles of only 20- to 22-gauge. The second most frequent cause of death after an abdominal guided biopsy is pancreatitis due to transgression of normal pancreatic parenchyma.

Needle track seeding is also a rare but major complication with a frequency ranging from 0.003% to 0.009%.¹⁰⁰ Most of the reported needle track seedings are the result of biopsies of pancreatic cancer, although virtually any tumor may spread along a needle track.

Tips and Tricks to Improve Outcome

Abscesses at Specific Locations

Conclusion

Intra-abdominal abscesses occur from a wide variety of causes and are characterized by accumulation of an infected fluid collection within the structures of the abdomen and pelvis. Depending on the etiology, the abscesses can develop either within the solid or hollow visceral organs or within the intraperitoneal and retroperitoneal spaces. Without timely and adequate drainage, intra-abdominal abscesses cause increased morbidity and mortality in spite of appropriate antibiotic coverage.¹⁻⁵ Image-guided percutaneous drainage provides a safe substitute to surgical débridement in the management of these abscesses.^{2-4,6-8} Advances in percutaneous techniques have resulted in abscess cure rates of more than 90%, and image-guided drainage is currently considered the preferred treatment option in the management of intra-abdominal abscesses.²⁻⁸ Higher cure rates in treatment of intra-abdominal abscesses have also resulted from improved diagnostic imaging techniques, such as computed tomography (CT) and magnetic resonance imaging (MRI), which allow early diagnosis and thereby timely intervention. Percutaneous catheter drainage of abscesses has several advantages over surgical lavage for treatment of intra-abdominal abscess. These include absence of a laparotomy scar, shorter hospital stay, avoidance of general anesthesia, lower risk of complications, and lower morbidity and mortality.^{3,7-10}

Rising use of CT and MRI in patients thought to have intra-abdominal sepsis has permitted early and accurate detection of abscesses. This is particularly true in patients with predisposing factors for development of abdominal abscesses, such as individuals with Crohn's disease, diverticulitis, and appendicitis,

and in postoperative patients after abdominal surgery.^{7-9,11,12} Imaging not only provides precise diagnosis but also guides interventional radiologists in safely draining the infected fluid collections. Despite the high success rates reported for percutaneous abscess drainage, it can at times be technically challenging because of the presence of fistulas, inaccessible locations, and comorbidities of the patient. In this chapter, our endeavor is to provide the reader with a synopsis of a radiologist's role in the diagnosis and management of intra-abdominal abscesses, particularly focusing on percutaneous abscess drainage.

Pathogenesis

The development of abscesses in the abdomen and pelvis is pathophysiologically similar to that elsewhere in the body, although the cause is often multifactorial.^{3,8,13} Intra-abdominal abscesses can arise from a wide variety of conditions but are commonly encountered in postoperative patients or in patients with infective or inflammatory diseases, such as inflammatory bowel disease, acute diverticulitis, or acute appendicitis.^{3,8,11-13} They can result from superinfection of a previously sterile fluid collection (e.g., postoperative biloma, hematoma) or arise de novo from an infectious nidus in a solid or hollow visceral organ (e.g., pyogenic liver abscess). In gross appearance, abscesses can have varied size and shape. Abscesses developing within solid visceral organs, such as liver and spleen, are often spherical or ovoid in configuration because of uniform pressure from surrounding tissue.^{3,14} Intraperitoneal and retroperitoneal abscesses have varied morphologic features and shape, depending on their location, spread along various fascial spaces, and pressure of surrounding structures.³ Mature abscesses often have a well-defined capsule composed of connective tissue (fibrin, collagen), blood vessels, and leukocytes.³ The contents of the abscess cavity gradually undergo liquefaction due to the enzymatic action of leukocytes.³ Bacterial isolates from abscess confirm the predominance of polymicrobial microorganisms in intra-abdominal infection.^{3,15}

Imaging Techniques

Technologic advancements in imaging techniques, particularly CT and MRI, have greatly enhanced their ability to accurately diagnose intra-abdominal abscesses. In addition to detection, imaging permits accurate depiction of extension of abscess across various fascial spaces in the abdomen.^{5,9,14,16} Imaging also aids the interventional radiologist in planning of interventional procedures for safe and effective drainage of the abscesses (Table 72-1).

PLAIN RADIOGRAPHY OR FLUOROSCOPY

Plain film radiography has a limited role in the diagnosis and management of intra-abdominal abscess. The radiographic

TABLE
72-1**Advantages and Disadvantages of Various Imaging Modalities in the Diagnosis and Management of Abscesses**

	Advantages	Disadvantages
Ultrasound	No radiation exposure Real-time nature helps avoid vessels, bowel, or pleural cavity Helps identify loculations and septations within abscesses Preferred for draining of superficial and unilocular abscesses	Limited role in drainage of collections deep in the abdomen Does not allow identification of complex abdominal fluid collections Limited role in the presence of ileus or extensive surgical wounds
Computed tomography	Modality of choice to drain complex abscesses in the retroperitoneum and mesentery Ideal for drainage of abscesses in postoperative patients with ileus and surgical wounds	Ionizing radiation exposure Considerable overlap in CT appearance of sterile and infected collections Abscesses of solid visceral organs can simulate soft tissue masses, often necessitating needle aspiration for differentiation
Magnetic resonance	Superior soft tissue resolution allows accurate diagnosis	Expensive Requires MR-compatible equipment
Fluoroscopy	When combined with ultrasound, fluoroscopy can be useful for performing drainage with Seldinger technique Helps demonstrate fistulous communication of abscesses with bowel and surrounding structures Helps in manipulation and repositioning of catheters with Seldinger technique	Lacks superior soft tissue resolution of cross-sectional imaging Accurate localization of catheter position often not possible

signs that are helpful in the diagnosis of intra-abdominal abscesses include an abnormal gas pattern, extraluminal air-fluid level, free intraperitoneal air, soft tissue mass, and loss of normal fat planes and interfaces.³ Nonetheless, plain radiography is an insensitive technique that is not reliable in day-to-day practice.³ Real-time fluoroscopy, on the other hand, is useful in guiding percutaneous drainage of abscesses in specific locations; for example, it can be used in conjunction with ultrasound to facilitate drainage of subphrenic abscesses while avoiding pleural transgression. Fluoroscopic guidance is also useful for aiding catheter manipulations, such as catheter repositioning and exchanges after initial placement of the percutaneous catheter.

ULTRASOUND

Ultrasound is often used as a screening modality for initial diagnosis of intra-abdominal fluid collections. Ultrasound has

several advantages over other imaging modalities; it is relatively inexpensive, easily available, and portable and does not use ionizing radiation.³ Ultrasound is particularly beneficial in rapid bedside diagnosis of abscesses in seriously ill patients in hospital intensive care units who are unable to travel to the radiology department for a CT scan.^{3,17} The ability to perform bedside ultrasound scans is especially valuable for guiding placement of percutaneous drainage catheters into abdominal abscesses in intensive care unit patients.^{3,17}

Ultrasound is also the preferred imaging modality for diagnosis and for guiding percutaneous drainage of superficially located abscesses and multiloculated collections.^{3,17,18} Because of its real-time nature, it also confers a low risk for traversing vascular structures, bowel, or the pleural cavity during ultrasound-guided abscess drainage.^{3,5,9,17,18} In patients with deep-seated pelvic abscesses, ultrasound also provides the opportunity for drainage through the transrectal or transvaginal route.^{9,17,18} In experienced hands, ultrasound allows rapid and accurate drainage of intra-abdominal abscesses compared with CT.^{3,17}

The sonographic appearance of abdominal and pelvic abscesses depends on their location and internal contents. In general, the abscesses are seen as anechoic to hypoechoic cystic collections with internal echoes and debris.^{3,5,18} More complex abscesses can have variegated hypoechoic and solid cystic appearance with irregular margins, internal septation, and debris (Fig. 72-1).^{3,5,18} Presence of gas within a fluid collection often demonstrates “dirty” shadowing and is highly suggestive of infection.^{3,5,18} The demonstration of multiloculations within a fluid collection is a valuable feature of ultrasound, which has important treatment implications because such abscesses often require insertion of multiple catheters or instillation of thrombolytic agents to facilitate optimal drainage.^{3,5,18-21} On occasion, the diagnosis of intraperitoneal abscesses can be challenging on ultrasound because of the need to differentiate these collections from surrounding fluid-filled bowel loops.^{3,18} The real-time nature of ultrasound aids in this differentiation by demonstrating peristalsis within bowel loops.^{3,18} The characteristic sonographic signature of the bowel wall is an additional differentiating feature. Doppler interrogation of intra-abdominal fluid collections is essential to rule out the possibility of pseudoaneurysms. This is particularly relevant in fluid collections adjacent to major vessels or in conditions with a high incidence of pseudoaneurysm formation, such as acute pancreatitis.

Ultrasound, however, has several limitations. Despite its value in abscess detection, ultrasound has a limited ability to define the spread of abscesses and inflammation across fascial planes within the abdomen. Ultrasound is highly operator dependent, and detection of fluid collections is rendered challenging in patients with ileus or those with extensive surgical wounds.^{3,18} For the same reason, ultrasound fares poorly in the detection of deep-seated abscesses in the retroperitoneum because of overlying bowel gas. Wound dressings and postsurgical drains also limit adequate visualization of intra-abdominal abscess.^{3,18}

COMPUTED TOMOGRAPHY

CT is the imaging modality of choice for initial diagnosis and management of patients with suspected intra-abdominal abscess.* CT allows precise anatomic localization of the abscess,

*References 3, 4, 9, 13, 18, 22-26.

Figure 72-1 Ultrasound features of intra-abdominal abscesses in three different patients.

A. Transverse sonographic image of a pyogenic liver abscess in a 46-year-old man shows a hypoechoic abscess with thick irregular wall and internal echoes and debris (arrows).

B. Sonographic image of a liver abscess in a 55-year-old woman showing a heterogeneous echotexture abscess (thin arrows) with multiple echogenic foci with dirty shadowing indicating air (thick arrow). **C.** Sonography of left upper quadrant in a 24-year-old man shows a complex multiseptate perisplenic abscess with internal debris (arrows).

defines its extent, and delineates its relationship to other intra-abdominal structures, such as bowel loops and vascular structures.* Multiplanar reformations (coronal and sagittal) are extremely valuable in defining abscess extent and in assessment of collections in the subphrenic location around the dome of the liver and the spleen. In patients with intra-abdominal sepsis and in postoperative patients, CT affects management by allowing detection of multifocal abscesses at distant locations within the abdomen and pelvis. CT is valuable not only for diagnosis of intra-abdominal abscess but also in the planning of percutaneous interventions.* CT is less successful in the depiction of internal septations within an abscess, a feature better visualized on ultrasound.

In patients thought to have an infected intra-abdominal process, CT should ideally be performed after the administration of intravenous and oral contrast media.^{3,4,26} Intravenous injection of contrast media not only improves abscess detection but also is essential for enhanced characterization of the abscess features, such as the abscess wall.^{3,5,18} The wall of a mature abscess demonstrates enhancement after injection of contrast media, and it remains a key feature in the diagnosis of intra-abdominal abscess.^{3,5,18} Ingestion of positive oral contrast media is preferred before the CT scan as it allows differentiation of abscesses from adjacent bowel loops because unopacified bowel loops can mimic an abscess^{2,3,5,18} (Fig. 72-2). Some authors advocate the use of delayed scans in different positions for differentiation of questionable areas of abscess from bowel loops as bowel loops generally change in position and configuration with change in the patient's position.³ Positive oral contrast media are often helpful in detecting the presence of

bowel perforation, particularly in patients presenting with intra-abdominal sepsis after bowel surgeries. Bowel perforation is diagnosed by extraluminal leak of the orally administered contrast material. Colonic perforations are less reliably depicted with orally administered contrast material and might require administration of rectal contrast. Instillation of rectal contrast material is optional but can be helpful in the differentiation of deep pelvic and perirectal abscesses.

Administration of an oral contrast agent, is however, not recommended for patients presenting for follow-up CT examination after initial catheter drainage of abdominal abscess. Because these patients might require catheter manipulations for optimal positioning of the drainage catheter, oral contrast media ingestion is not recommended if the patient is to shortly receive conscious sedation.

On CT, abscesses often have fluid attenuation with internal attenuation measurements ranging between 0 and 25 HU.^{3-5,18} The density of an abscess largely depends on the abscess contents, degree of liquefaction, and presence of gas (Fig. 72-3).^{3-5,18} The abscess wall often appears as a high-density irregular peripheral rim that enhances after contrast medium injection.^{3-5,18} Abscess wall enhancement is considered to be a sign of abscess wall maturation and therefore predicts favorable response to percutaneous drainage.^{3-5,18} The abscess contents often do not enhance because of the ongoing process of liquefaction and lack of internal vascularity; internal enhancement in a suspected abscess should therefore raise concern for underlying tumor.³ Gas within a fluid collection is highly diagnostic of an abscess and is seen in up to 50% of infected intra-abdominal fluid collections (Fig. 72-3).^{3-5,18} Gas can be seen as either small locules and air pockets or air-fluid levels. Presence of gas within a collection could be due to infection with anaerobic organisms, fistulous communication with bowel, or prior

*References 3, 4, 9, 13, 18, 22-26.

Figure 72-2 Value of CT positive oral contrast media in the diagnosis of intra-abdominal abscess. Axial (A), coronal (B), and sagittal (C) reformatted CT images of postoperative abscess in a 36-year-old man with Crohn's disease. Administration of positive oral contrast medium allows accurate differentiation of bowel loops from interloop abscesses (arrows). D and E. Axial and sagittal reformatted CT images of periappendiceal abscess (arrows) in a 24-year-old show the abscess clearly separated from contrast-opacified bowel loops.

interventions. Demonstration of large amounts of air in intra-peritoneal or retroperitoneal collections should raise concern for possible fistulous communication with bowel loops.^{3-5,18,27,28} Bowel communication could be due to either bowel perforation or the primary cause of the abscess itself, such as Crohn's disease or diverticulitis.^{3,27-29}

Typically, an abscess within a solid visceral organ is ovoid or spherical in shape, whereas intraperitoneal or retroperitoneal abscesses have varied morphology because they conform to the shape of the compartment in which they are located and often displace surrounding structures. The adjacent fascial planes may be obliterated or thickened by spread of inflammation, and surrounding mesenteric fat can show increased

attenuation.^{3,18,24,26} The CT appearance of sterile and infected fluid collections can show a substantial degree of overlap. On CT, abscesses of solid visceral organs can simulate soft tissue masses.^{2,7,18} Not infrequently, needle aspiration is required to differentiate between an abscess and solid mass.^{2,7,18}

MAGNETIC RESONANCE IMAGING

In the past few years, there has been an increasing trend in the use of MRI for diagnosis of intra-abdominal abscesses. MRI offers several advantages over CT, the chief ones being the absence of ionizing radiation and the superior soft tissue resolution. MRI is particularly preferred in pediatric patients and

Figure 72-3 CT features of intra-abdominal abscesses in two different patients. **A.** Axial CT image in a 62-year-old man with perinephric abscess shows a low-attenuation collection in the left perinephric space with enhancing wall (arrows) at the periphery and mild surrounding fat stranding. **B.** Axial CT image in a 65-year-old woman with a postoperative abscess after laparoscopic cholecystectomy shows a perihepatic abscess with air-fluid level (arrows).

Figure 72-4 MRI in diagnosis of intraperitoneal abscess. **A.** Axial T2-weighted image demonstrates a right lower quadrant abscess (arrows) in a 24-year-old man with Crohn's disease. The abscess demonstrates heterogeneous T2 hyperintensity. **B.** Post-gadolinium-enhanced fat-suppressed T1-weighted image shows intense peripheral enhancement of the abscess wall and the surrounding structures, indicating inflammatory involvement (arrows).

young adults because of the concerns about the harmful effects of ionizing radiation. This is particularly true in patients with Crohn's disease, who often undergo multiple cross-sectional imaging studies in their lifetime, and intra-abdominal abscesses frequently complicate their clinical course. MRI has a problem-solving role in the characterization of complex adnexal lesions in women of reproductive age and aids in the diagnosis of tubo-ovarian abscesses.

The routine use of MRI for detection of abscess is however limited by the lack of MRI expertise, high cost, and long scanning times in abdominal MRI examinations. It is also difficult to perform good-quality examinations on critically ill patients.

On MRI, intra-abdominal abscesses typically demonstrate inhomogeneous areas of hypointensity on T1-weighted images and intermediate intensity to hyperintensity on T2-weighted images (Fig. 72-4).^{3,4} After intravenous administration of gadolinium, the abscess demonstrates intense wall enhancement as on CT.^{3,4}

SCINTIGRAPHY

Nuclear scintigraphy has a limited role in the diagnosis of intra-abdominal abscesses and is often not the first-line imaging investigation to be performed. Scintigraphic studies are often obtained in patients with suspected intra-abdominal sepsis or abscess when other diagnostic modalities, such as ultrasound, CT, or MRI, have yielded negative results.^{3,18,30} The most

commonly used isotopes for detection of abscess are gallium (Ga 67) and indium (In 111) to label white blood cells.^{3,18,30,31} Newer scintigraphic agents, such as technetium Tc 99m HMPAO-labeled white blood cells, ¹¹¹In-labeled polyclonal immunoglobulin G, and ^{99m}Tc-labeled monoclonal antibodies, have also been reported to improve diagnosis of intra-abdominal abscess.³ ⁶⁷Ga scans, although sensitive, have limited specificity for abscess diagnosis because of false-positive results in conditions such as granulomatous disease, lymphoma, and normal gut.³ One of the main limitations of nuclear scintigraphic studies in the characterization of abdominal abscesses is the poor anatomic detail of these scans, which limits their value in planning of percutaneous interventional procedures.^{3,18}

Imaging-Guided Intervention

Percutaneous catheter drainage is a safe and effective means for treatment of the entire gamut of intra-abdominal abscesses irrespective of their cause and anatomic location.* Percutaneous catheter drainage is widely considered the first-line treatment option for management of intra-abdominal abscesses, superseding surgical drainage.* Percutaneous catheter drainage of abscesses is less invasive compared with surgery and is associated with fewer postprocedural complications, such as

*References 1, 2, 5, 7-10, 18, 24, 32, 33.

atelectasis, pneumonia, pain, and venous thrombosis.^{3,9,10,18} A combination of high success rate and low complication rate has made percutaneous drainage a mainstay in the treatment of abdominal abscess.

DIAGNOSTIC ASPIRATION

In patients with clinical and imaging confirmation of an intra-abdominal abscess, the definitive treatment is percutaneous drainage through a catheter. However, in certain circumstances in which the imaging features are not conclusive for the presence of pus, simple diagnostic aspiration of the fluid collection is indicated.^{2,9,18} Fine-needle aspiration of small amounts of fluid permits laboratory evaluation of fluid chemistry and microbiology.^{2,18} Diagnostic needle aspiration of fluid collections is also valuable as a temporizing measure before surgical intervention in anatomically difficult locations like the pelvis to render the surgical field clean.^{2,9,18}

Diagnostic needle aspiration of fluid collections is usually accomplished with a 20- or 22-gauge Chiba needle.^{2,9,18} The placement of the needle into the collection can be guided with either ultrasound or CT (Fig. 72-5). The type of fluid aspirated from the needle often dictates the next strategy. If pure pus is extracted, the drainage catheter is immediately placed. If no pus is obtained, a Gram stain can be performed to assess the origin and cause of the contents. If Gram stain of the contents reveals leukocytes without bacteria, it is likely to be a sterile abscess, which is typically seen in hospitalized patients who have already been administered antibiotics.⁹ If Gram staining reveals leukocytes and bacteria, it is likely to be an abscess and requires catheter drainage.⁹ If there are bacteria without leukocytes, the possibilities include abscess in an immunocompromised patient and a likelihood of fistulous communication with bowel. Aspiration is not indicated if the collection has potential

communications with bowel, the biliary system, or the urinary tract.^{2,9,18} Aspiration is ineffective in these situations as immediate reaccumulation of the collection occurs after initial successful percutaneous aspiration and needle removal.² In addition to Gram stain, the extracted fluid should also be sent for fluid chemistry analysis to study fluid characteristics because the radiologic signs of abscesses, hematomas, urinomas, bilomas, postoperative seromas, and even loculated ascites can often overlap.^{2,9,18} Accordingly, analysis of fluid chemistry leads to recognition of the source of the fluid collection (e.g., urinomas demonstrate elevated creatinine concentration, bilomas are characterized by elevated bilirubin levels, and pseudocysts show amylase).^{2,9,18}

PERCUTANEOUS ABSCESS DRAINAGE: CLINICAL CONSIDERATIONS

Indications

Appropriate patient selection is important before percutaneous drainage as improper patient selection with incomplete drainage often leads to an increase in morbidity. The typical indication for image-guided percutaneous drainage is the presence of an intra-abdominal fluid collection with features of abscess in the background of abdominal pain, fever, and leukocytosis.^{2,3,9,18} The goal of drainage in these circumstances is palliation and treatment of sepsis associated with the infected fluid collection. Another common indication for percutaneous drainage is for alleviation of symptoms caused by the size of the fluid collection (e.g., in pancreatic pseudocysts).^{34,35}

Contraindications

Percutaneous abscess drainage is contraindicated in patients with severe uncorrectable coagulopathy and thrombocytopenia as they predispose to increased risk of bleeding.³⁶ Other relative

Figure 72-5 Diagnostic aspiration of postoperative fluid collection after mesh repair. **A.** Sagittal reformatted CT image shows an anterior abdominal wall fluid collection (white arrow) in a 75-year-old man after ventral hernia mesh repair (black arrow). **B.** Diagnostic aspiration was performed under CT guidance with a 20-gauge needle (thin arrow) to confirm presence of infection in the collection (thick arrow). Gram stain showed gram-negative rods and a percutaneous drainage catheter was subsequently placed.

contraindications for abscess drainage are severely compromised cardiopulmonary function and hemodynamic instability.³⁶ In these situations, efforts should be made to improve clinical status to a level at which the drainage procedure can be safely performed. Lack of a safe trajectory to the abscess for optimal drainage because of overlying vital structures is another relative contraindication.^{2,3,36} However, in many of these situations, changes in the patient's position or other maneuvers can often create a safe pathway for successful drainage.

There are several situations in which image-guided abscess drainage, although not contraindicated, should be avoided.² When free hollow organ perforation occurs as evidenced by a large amount of intraperitoneal free air, an open surgical procedure should be primarily considered.² Similarly, acute peritonitis is best managed by immediate surgical intervention, although in dire settings when a patient is considered unfit for surgical treatment, percutaneous catheter drainage could be performed.² Symptomatic noninfected fluid collections in the vicinity of surgical implants of any type, including vascular grafts, hernia repair mesh, and joint prosthesis, should not be drained unless they are superinfected.² Percutaneous catheter drainage of these noninfected fluid collections could potentially risk infection of the implants.² In these situations, infection can be confirmed with diagnostic fine-needle aspiration (Fig. 72-5).² In addition, drainage of noninfected pelvic collections through a transvaginal route is not appropriate.^{2,5,18} Collections related to pancreatic abscess or pancreatitis are usually refractory to percutaneous drainage compared with intra-abdominal abscesses from other sources.^{2,5,18} A multidisciplinary approach is needed in these patients, that is, collaboration with endoscopic methods to facilitate resolution of the collections by placement of cystogastrostomy stents.^{2,5,18}

Role of Antibiotics

Effective management of intra-abdominal abscess needs administration of intravenous antibiotics in addition to prompt percutaneous drainage. Prophylactic antibiotic coverage is also essential before image-guided abscess drainage to prevent septic complications due to transient bacteremia resulting from the drainage of intra-abdominal abscess.^{2,3,18} Adjunctive antimicrobial therapy must be directed at enteric gram-negative rods, gram-positive cocci, and anaerobes.^{2,3,18}

Preprocedure Work-up

A comprehensive patient work-up including informed consent is indispensable before the procedure.³⁷ Before abscess drainage, details including the technique and the complications and effectiveness of the procedure should be explained to the patient and the family, and written informed consent should be obtained. During the consent process, it is essential to explain to the patient and the family about the need for regular care of the drainage catheter after the procedure. It is equally important to communicate to the patient and the family that often the drainage catheters need to be retained in place at least for a few weeks before they are removed.

The necessary preliminary work-up includes laboratory evaluation of complete blood count, coagulation profile (international normalized ratio should be <1.5, activated partial thromboplastin time normal 25-35 sec, platelet count >50,000).^{3,7,9,38} The recent imaging studies including CT and MRI should be carefully reviewed to determine the abscess number, size, and location and the extent of involvement.^{3,7,9} In

general, the yield of drainage in abdominal abscesses smaller than 2 cm is low because the diameter of the pigtail catheter is more than 2 cm.* Preprocedure imaging should be carefully reviewed to plan the drainage procedure by giving special consideration to the proposed path of the drainage catheter. Careful interrogation is also essential to avoid inadvertent catheter drainage of infected pseudoaneurysms, which can lead to catastrophic bleeding. Color Doppler ultrasound and contrast-enhanced CT or MRI are key to making this diagnosis. It is also important to carefully review the preprocedural diagnostic imaging studies to avoid bowel transgression and vascular injury. To avoid inadvertent injury to superficial vessels in the abdominal wall, such as epigastric arteries, it is crucial to review the diagnostic contrast-enhanced CT or MRI study to map the location of these vessels. In addition, one can perform color Doppler ultrasound before the percutaneous drainage to map the location of these vessels.

Catheter Selection

Wide ranges of drainage catheters are available with diameters varying from 6F to 18F.[†] The selection of catheter is performed on the basis of several factors, including the size of the collection and the nature and the viscosity of the fluid obtained during initial needle placement immediately before catheter placement.[†] In general, smaller 8F to 12F catheters can be used successfully for initial percutaneous drainage. The newer catheters have hydrophilic coating (capability of absorbing and retaining water when wet), which reduces their friction coefficient and substantially improves the ease of insertion. Catheters with an internal locking pigtail configuration are preferred for retention. Larger catheters are generally preferred in abscesses with thick and viscous abscess contents.^{18,19} Percutaneous drainage of complex abscesses is sometimes limited despite appropriate positioning of catheters.¹⁹ Catheter selection in such situations is of crucial importance as increasing catheter size and number of catheter side holes often allows effective drainage of difficult abscesses.¹⁹

Patient Positioning

Planning of the patient's position is vital to successful abscess drainage; not only does this determine a safe percutaneous path to the abscess, but optimal positioning ensures the patient's comfort and minimizes motion during the procedure. An ideal position is one that allows the shortest and least complicated access to the abscess by avoiding vital structures such as bowel and vessels. The positioning during the procedure is often dependent on the location of the abscess and the planned percutaneous path for the drainage catheter. In most cases, successful drainage of the abscess can be performed with the patient in the supine position. The other common positions are prone, lateral decubitus, and lateral oblique positions.

Patient Preparation

Percutaneous drainage of intra-abdominal abscess is often performed in hospitalized patients but can also be done on an outpatient basis. When it is performed on an outpatient basis, it might be necessary to admit the patient for overnight observation on the basis of the patient's clinical condition. Before the

*References 5, 6, 9, 18, 32, 39.

†References 2, 5-9, 18, 19, 32, 39.

procedure, the patient should be fasting for at least 8 hours, and anticoagulant medications should be discontinued before the procedure. The patient should, however, continue other medications in the preoperative period. The procedure is mostly performed under intravenous conscious sedation, but general anesthesia should be considered in critically ill patients. Cardio-respiratory monitoring including electrocardiography, blood pressure, and pulse oximetry are crucial for monitoring of the patient during the procedure.

PERCUTANEOUS ABSCESS DRAINAGE: TECHNIQUE

After the details of the procedure and the associated risks are explained, the patient is placed on the procedure table in a position most optimal for a safe drainage as determined by the preprocedural imaging. During ultrasound-guided abscess drainage, a preliminary real-time scan is performed to identify the percutaneous needle path to the abscess. After the path is identified, color Doppler ultrasound should be used to determine if any intervening vessel lies in the proposed path. It is also crucial to interrogate the abscess with color Doppler to avoid placing a drainage catheter in a pseudoaneurysm, which could lead to catastrophic bleeding. Once a safe path is identified, the skin over the needle entry site is marked with a skin marker. Similarly, during CT-guided procedures, a preliminary CT scan is obtained to localize the abscess and to determine the path of the needle. Just as in ultrasound, review of the preprocedural imaging is critical to identify any vessels in the needle path. The skin entry site for the needle and the catheter are then cleansed with antiseptic solution, and the site is draped with sterile drapes to create a sterile field.

There are two basic techniques for percutaneous drainage of intra-abdominal abscesses, namely, the trocar technique and the Seldinger technique. Both these techniques are equally effective and have their distinct advantages and disadvantages (Table

72-2). The choice of technique to drain a particular abscess is mostly dependent on the preference of the interventionalist and the size, shape, and location of the abscess.

Trocar Technique

In this technique, a catheter is mounted on a metal cannula–sharp trocar system and introduced into the abscess directly or in tandem with a guiding needle.^{2,25} Direct trocar technique is often performed when the abscess drainage is performed under ultrasound guidance (Fig. 72-6). In this technique, after the

TABLE 72-2

Advantages and Disadvantages of Image-Guided Percutaneous Drainage Catheter Techniques

	Advantages	Disadvantages
Trocar technique	Allows rapid deployment of catheters Best suited for uncomplicated well-defined collections, particularly in solid organs	Difficulty of repositioning a catheter that has been initially deployed suboptimally Not preferred for complicated ill-defined collections in open spaces (retroperitoneum or mesentery)
Seldinger technique	Allows the ability to direct the wire to the precise location desired for catheter deployment Allows accurate placement in large complex abscesses, such as those in subphrenic locations and where access is tightly restricted	Difficulty in working in confined spaces Multiple steps involved in dilation Under CT guidance, any buckling or kinking of the wire and dilators can be a problem

Figure 72-6 Trocar technique for placement of percutaneous drainage catheter. **A.** Illustration shows the placement of the catheter-cannula-trocar system into the abscess. This is followed by the catheter being fed off over the cannula-trocar. The final image shows the catheter positioned within the abscess cavity. **B and C.** Ultrasound-guided placement of drainage catheter (thin arrow) into a liver abscess (thick arrow).

direct path to the abscess is identified, local anesthetic is administered and a skin incision is made at the planned skin entry site wide enough to accommodate the catheter. Blunt dissection is then performed at the incision site to facilitate easy passage of the catheter.²⁵ The preselected drainage catheter is then mounted onto a metal stiffening cannula and inner trocar.^{2,25} Subsequently, the catheter loaded on the trocar and the cannula are then advanced into the abscess under direct visualization by real-time ultrasound.²⁵ Once the tip of the catheter-trocar system is within the abscess, the catheter is fed off of the cannula and trocar into the abscess cavity.²⁵ Pulling on the string then forms the pigtail of the catheter, and the catheter is connected to a bag for gravity drainage.²⁵

The tandem trocar technique is most often employed when the drainage catheter placement is performed under CT guidance, during which the catheter-trocar system is inserted into the abscess parallel to a guiding needle.^{25,36} The initial step in this technique involves placement of a guiding needle at the planned skin entry site after subcutaneous infiltration with 1%

lidocaine.²⁵ The guiding needle, which is usually a 20-gauge needle (Chiba biopsy needle), is slowly advanced under imaging guidance into the abscess. Accurate placement of the guiding needle is crucial to ensure safety of this technique and also permits precise deployment of the catheter in an appropriate position.^{25,36} Because the portion of the needle outside the body serves as a guide for subsequent catheter placement, the length of the needle should be appropriately selected such that a substantial portion of the needle extends outside the skin as the needle is firmly positioned inside the abscess (Fig. 72-7).^{25,36} It is key to have several centimeters of the guiding needle outside the skin because the outer portion of the localizer needle directs the appropriate trajectory and angle of entry of the catheter into the abscess even if the shape of the abscess is affected by respiratory or other motion.^{25,36} After accurate positioning of the needle within the abscess is confirmed, the catheter is placed adjacent to the needle in tandem to it.³⁶ A small incision is made in the skin adjacent to the needle, and blunt dissection is done to allow placement of the catheter.^{25,36} For accurate positioning

Figure 72-7 Tandem trocar technique for percutaneous abscess drainage. **A.** Axial CT image shows initial placement of a 20-gauge Chiba needle (arrow) into an anterior abdominal fluid collection. **B.** Subsequently, the drainage catheter (thin arrow) is placed in tandem and parallel to the guiding needle (thick arrow). **C.** Final CT image shows the drainage catheter (arrow) placed appropriately in the abscess with the pigtail within the collection.

of the catheter, the depth of the abscess cavity from the skin entry site is measured and appropriate marking is made on the catheter. The catheter-trocar system is then advanced alongside the needle, holding it perfectly parallel to the guiding needle to the predetermined depth.^{25,36} When the catheter has been advanced to the premeasured depth, feeding the catheter over the trocar-cannula system deploys the catheter. The catheter tip position within the abscess cavity is then ascertained by obtaining postprocedure CT images. If the position of the catheter is deemed satisfactory, it is secured externally and connected to a bag drainage system.

Seldinger Technique

The Seldinger technique encompasses the placement of a drainage catheter into an abscess over a guidewire, which is positioned into the abscess through a needle (Fig. 72-8).^{25,36,40} The first step in this procedure involves introduction of a needle into the abscess cavity through a safe percutaneous path as described before.^{25,36,40} The needle should be an 18-gauge or 19-gauge sheathed needle to accommodate a 0.035- or 0.038-inch guidewire for placement of 8F to 14F catheters (Fig. 72-9).^{25,36,40} Once the position of the needle in the abscess cavity is confirmed, the inner stylet of the needle is removed, and the guidewire is threaded into the needle and positioned within the abscess cavity.^{25,36,40} The catheter is then deployed into the abscess cavity over the guidewire after serial dilation with fascial dilators to the required catheter size.^{25,36,40}

Despite the technique used (i.e., trocar or Seldinger), it is essential to ensure that the catheter is appropriately positioned within the abscess.³ In general, for effective drainage, the

catheter tip should be ideally positioned within the most dependent portion of the abscess.³ In abscesses with complex shape, the catheter tip should be positioned within a location distal to the catheter entry site, and preferably the side holes should be spread out within the abscess to help effective drainage.³

Catheter Fixation

After placement of the abscess drainage catheter, the catheters are retained in place within the abscess cavity by internal and external retention mechanisms. Internal retention is achieved by the nature of the locking pigtail catheters, which prevents inadvertent catheter withdrawal.³⁶ The pigtail is formed with the help of a string, which courses through the catheter and is secured near the catheter hub.³⁶ The string has a protective mechanism as well to prevent catheter rupture within the patient as the string usually breaks when excessive tension or pressure is applied.³⁶ For external fixation, the catheter is fixed outside the body by taping or sewing it to different types of fixation devices that are left adherent to the skin.³⁶ External fixation devices preclude the need for suturing of the catheter to the patient's skin, which not only can be an irritant but also can be a focus of infection.³⁶

ADDITIONAL TECHNIQUES FOR ABSCESS DRAINAGE

Organ Traversal

On occasion, percutaneous access into abdominal abscesses is not possible without crossing an intervening organ.² In several

Figure 72-8 Seldinger technique for percutaneous abscess drainage. **A.** Illustration shows initial placement of a 19-gauge needle into the abscess. **B.** In the next step, a guidewire is introduced through the needle into the abscess cavity. **C.** After a sufficient length of guidewire is coiled in the abscess cavity, the track is serially dilated over the guidewire using fascial dilators to enable placement of a drainage catheter. **D.** The percutaneous drainage catheter is then placed into the abscess after passing over the guidewire. **E.** The final image shows appropriate positioning of the percutaneous catheter within the abscess.

Figure 72-9 Seldinger technique for drainage of a large intraperitoneal abscess. **A.** Preliminary axial CT image shows the placement of an 18-gauge needle (arrow) into the intraperitoneal abscess. **B.** Subsequently, a guidewire (arrows) was introduced into the collection through the needle. **C** and **D.** After serial dilation over the guidewire, a 12F multi-side hole drainage catheter (arrows) was placed into the collection, resulting in adequate drainage.

circumstances, the drainage catheter can traverse intervening organs without undue complications.²

The organs that can be safely traversed in most circumstances are the stomach and the liver (Fig. 72-10).² It is also safe to traverse the rectum and the vagina with use of the transcavitary approach for abscess drainage.²

Several organs, however, should not be traversed and should be carefully avoided during percutaneous abscess drainage, namely, the pancreas, spleen, gallbladder, small and large bowel, urinary bladder, uterus and ovaries, prostate, and blood vessels.² Although percutaneous drainage of abscesses within these organs is safe, these organs should not be transgressed in an attempt to reach a deep-seated abscess.²

It is important to take several important precautions to ensure safe traversal of intervening organs.² In traversing structures such as the liver, it is important to make sure that the coagulation parameters are normal.² Also ensure that the catheter has the shortest possible course through the liver, at a safe distance from major blood vessels, dilated biliary ducts, and gallbladder.² In addition, care should be taken that the catheter side holes are totally confined within the abscess cavity to avoid contamination of the adjacent liver or biliary tract.²

The stomach is frequently traversed for percutaneous drainage of pancreatic abscess or pseudocysts.² In these situations, a multi-side hole catheter is used, and it is positioned such that the side holes are situated within both the pancreatic or peripancreatic collection and the stomach.² To promote formation of a cystogastrostomy track, the catheter should be left in place for 6 weeks. This allows drainage of the pancreatic duct secretions into the stomach because of the presence of a communication between the pancreatic duct and the pseudocyst.²

CT Gantry Angulation

Angulation of the CT gantry is a useful technique to create a safe pathway for drainage of deep-seated abscesses when all the planned access routes in the axial planes have bowel, bone, and blood vessels in their paths.^{2,41,42} Angling of the gantry in a cranial or caudal direction generally helps create a safe path to the abscess that avoids vital organs.^{2,41,42} For example, if an abscess is located high in the pelvis, angulation of the CT gantry in the cephalic direction can facilitate transgluteal drainage (Fig. 72-11).^{2,41,42} When this approach is used, careful attention to technique is required because the needle and the catheter should be aligned parallel to the angled gantry for optimal positioning.^{2,41,42}

Surgical Drains as Access Route for Abscess Drainage

Preexisting surgical drains provide a safe and effective alternative access route for percutaneous drainage of less accessible deep-seated postoperative abdominal abscesses (Fig. 72-12).⁴³ This is particularly true for deep-seated intra-abdominal fluid collections that cannot be accessed safely from a percutaneous approach.⁴³

Combined Modality Approach

Abscesses in difficult locations that cannot be accessed with guidance from a single imaging modality can be effectively drained by a combination of imaging modalities, like ultrasound and fluoroscopy.^{2,3,9,18,36} In these situations, after initial placement of the needle into the abscess with ultrasound, fluoroscopy allows real-time navigation of the catheter and

Figure 72-10 Organ traversal technique for percutaneous abscess drainage. **A.** Contrast-enhanced axial CT image shows an abscess (*thin arrows*) posterior to the left lobe of the liver (*thick arrow*). **B.** Percutaneous abscess drainage was performed with successful placement of the drainage catheter into the abscess (*thin arrow*) after traversing the lateral portion of the left lobe of the liver (*thick arrow*). **C.** Contrast-enhanced axial CT image shows a bilobed infected pancreatic pseudocyst (*thin arrows*). The drainage catheter is indicated by the thin arrow. **D.** Percutaneous drainage of this abscess necessitated traversal of the stomach (*thick arrow*). The stomach is indicated by the thick arrow.

Figure 72-11 Gantry angulation technique for drainage of subphrenic abscess. **A.** Preliminary axial CT image demonstrates a subphrenic abscess (*asterisk*) surrounded posteriorly by lungs (*arrow*). **B.** Gantry angulation was performed, which resulted in creation of a safe trajectory without intervening lung (*arrow*). **C.** Procedural CT image shows placement of an 18-gauge Chiba needle (*small arrow*) into the abscess cavity (*large arrow*). **D.** After successful abscess drainage, the catheter is seen within the collapsed abscess cavity (*arrow*).

Figure 72-12 Use of surgical drain as an access for percutaneous drainage. **A.** Contrast-enhanced CT image shows a postoperative abscess (arrows) in the pancreatic bed not effectively drained by a surgical drain. **B.** Under fluoroscopic guidance, a guidewire was passed through the surgical drain to gain access into the abscess cavity. A Kumpke catheter was then passed over the wire into the abscess. Injection of contrast material in the image shows the peripancreatic abscess (arrows). **C.** Subsequently, the Kumpke catheter was exchanged for a wire, and a 12F multi-side hole drainage catheter was placed into the deep peripancreatic abscess with decompression of the abscess cavity (arrows).

guidewire into the desired location within the abscess.^{2,3,9,18,36} For example, fluoroscopy and ultrasound or CT can be used in combination to successfully drain abscesses in the subphrenic location while at the same time avoiding pleural transgression (Fig. 72-13).^{2,3,9,18,36}

Hydrodissection

Hydrodissection is an organ displacement method for creating a safe percutaneous trajectory for abscess drainage when adjunctive measures such as gantry angulation and patient positioning are not successful.⁴⁴ It involves instillation of 0.9% saline solution with a 20-gauge Chiba needle into the planned path for placement of the drainage catheter (Fig. 72-14).⁴⁴ The instilled saline then displaces the intervening structures away from the path to the abscess, allowing safe placement of the drainage catheter.⁴⁴ Hydrodissection is most effective for displacement of retroperitoneal structures, such as colon and duodenum, away from the path to deeper intraperitoneal abscesses.⁴⁴

CATHETER MANAGEMENT AFTER DRAINAGE

Immediately after Drainage

After initial catheter drainage, it is essential to completely evacuate the abscess contents and to irrigate the abscess cavity with saline several times until the aspirate becomes clear.^{8,18} The irrigation of the abscess must be performed with saline flushes

with a volume smaller than the abscess volume to avoid an ensuing increase in intracavitary pressure, which could potentially lead to bacteremia and sepsis.^{5,8,9,18,36} The catheter tip is positioned in a gravity-dependent location of the abscess to facilitate effective drainage.^{8,18} After successful placement of the drainage catheter and evacuation of the abscess cavity, it is essential to obtain postprocedure imaging to identify any additional collections or undrained loculations before completion of the procedure.^{8,18} Postprocedure imaging also allows detection of any complications related to the procedure, such as bleeding or pneumothorax.

Regular Catheter Care

After percutaneous abscess drainage, daily ward rounds are imperative to assess the patient's clinical response and to monitor catheter functioning.^{18,45} Daily rounds are also critical in fostering a good patient-physician relationship because a majority of patients are unaware of the existence of the interventional radiology service.^{18,45} The patients also appreciate the opportunity to interact with the radiologists, and the interaction in turn helps the radiologist to educate the patients about regular catheter care. The daily rounds should be used to assess the patient's clinical status, including the development of any postprocedure complications.^{18,45} The catheter function should be monitored to document drain output and any change in appearance of drain fluid.^{18,45} The catheter should be irrigated at least a few times daily with saline flushes (5-10 mL) to avoid

Figure 72-13 Combined modality approach for drainage of a subphrenic abscess.

A. Contrast coronal CT image shows a postoperative left subphrenic abscess (arrows) after splenectomy. The intercostal approach was not preferred because of potential for pleural transgression. **B.** Under ultrasound guidance and through a subcostal approach, a 19-gauge ultrathin Chiba needle (arrow) was placed into the subphrenic abscess. **C.** Fluoroscopic image shows the needle (arrow) with the tip in the left subphrenic region. **D.** Fluoroscopic image demonstrates placement of a drainage catheter in the left subphrenic space after serial dilation over a wire (arrows). **E.** Injection of contrast material into the catheter under fluoroscopic guidance shows opacification of the abscess cavity (arrows), which was subsequently drained.

clogging of the catheter and connecting tubing.^{18,45} The catheter position, exit site, and dressing should be carefully examined to ensure that the catheter is not retracting from the abscess.^{2,3,8,18} The daily rounds are also helpful to review the need for follow-up imaging and to decide the timing of catheter removal.^{18,45}

Post-Catheter Drainage Imaging and Catheter Removal

The timing for imaging assessment of the abscess after catheter drainage depends on several factors, including the patient's clinical status, laboratory findings, and daily drain output. In

Figure 72-14 Hydrodissection technique for drainage of deep pelvic abscess. **A.** Preliminary CT image shows a deep pelvic abscess (asterisk). A safe pathway to the abscess is blocked by the rectum posteriorly (thin arrow). A lateral percutaneous access to the abscess (thick arrow) is hindered by presence of blood vessels. **B.** A 20-gauge Chiba needle was introduced lateral to the rectum, and saline (arrows) was instilled through the needle to displace the rectum medially. **C.** Subsequent CT image shows the needle placed into the abscess through the percutaneous path created by saline instillation (arrows). **D.** Procedural axial CT image shows a safe pathway created by hydrodissection, which allowed placement of the drainage catheter (arrows) into the abscess through the transgluteal approach.

general, repeat imaging is often performed 1 to 2 weeks after initial abscess drainage. Cross-sectional imaging techniques such as CT are most commonly used to monitor the adequacy of drainage by determining the residual abscess volume as well as the development of new abscesses.^{9,18} However, MRI could be used for postprocedure imaging, particularly in pediatric patients. If CT shows that the abscess is totally resolved, catheter removal could be contemplated on the basis of the nature and quantity of drainage fluid (Fig. 72-15). If CT shows residual abscess in spite of optimum position of the catheter, the patency of the catheter should be confirmed by a 5- to 10-mL saline flush.^{9,18-20,29} If the catheter is patent and well positioned within the abscess but imaging shows persistence of the abscess, the catheter should be exchanged for a larger catheter or a catheter with more side holes to improve drainage.^{9,18-20,29} Fluoroscopic injection of iodinated contrast medium through the catheter should also be performed on the same day as the CT scan to look for any residual abscess and to document presence of a fistulous communication.^{9,18-20,29}

The percutaneous drainage catheter can generally be safely removed when the following criteria are met: resolution of clinical findings, including fever, pain, and leukocytosis; minimal drainage output (<10 mL in 24 hours); imaging findings demonstrating resolution of the abscess with absence of any residual collection; and fluoroscopically guided injection of contrast material demonstrating absence of fistulous communication of the abscess cavity with bowel or other structures close to the abscess cavity. Although diminishing drain output is an important indicator of effective abscess drainage, it is important to ensure that the reduction in drain output from the catheter is not due to other reasons, such as catheter malpositioning or blockage. In fact, whenever there is a sudden decrease in drain output, the possibility of catheter obstruction or kinking should be considered. Sudden increases in drainage could indicate fistulous communication with bowel or ascites drainage. These facts underscore the value of obtaining repeated imaging after catheter drainage to confirm abscess resolution and appropriate catheter position before contemplating catheter removal.

Figure 72-15 Post-percutaneous drainage abscess follow-up. **A.** Contrast-enhanced axial CT image shows a postoperative abscess (arrows) in the right lower quadrant after appendectomy. The abscess was drained by percutaneous drainage. **B.** Follow-up contrast-enhanced CT scan after 2 weeks demonstrates complete resolution of the right lower quadrant abscess (arrow). **C.** Fluoroscopically guided injection of contrast material into the catheter showed no residual abscess cavity and absence of any fistulous communication with bowel loops (arrows). The catheter was successfully removed.

FACTORS AFFECTING OUTCOME OF ABSCESS DRAINAGE

Successful drainage of intra-abdominal abscesses by percutaneous catheters relies on several important factors.^{6,19,20} A key factor facilitating adequate drainage is the appropriate placement of the catheter within the abscess cavity.^{6,19,20} The abscess size or volume as estimated by imaging is also important for selecting the catheters of appropriate size and length to enable unimpeded drainage.^{18,20,46} The density of abscess contents on CT has been reported to influence the success of abscess drainage.² An abscess with an attenuation of more than 20 HU has a higher failure rate compared with an abscess with a fluid attenuation of less than 20 HU.^{6,19} Abscesses with higher fluid attenuation might have increased levels of protein, blood products, and bacteria, which can impede catheter drainage.^{2,3,6,18,19} Complexity of abscess fluid, such as multiloculation and increased viscosity of internal contents, is associated with a lower rate of success.^{2,3,6,18,19} The relative efficacy of the initial drainage catheter is an important predictor of response to abscess drainage.^{2,3,6,18,19} This means that the abscesses that have a lower residual abscess volume as a percentage of initial volume have better treatment success than those with larger volume^{2,3,6,18,19} (Table 72-3).

After successful drainage of intra-abdominal abscesses, they can often recur at the same location.^{18,20,46} In such circumstances, repeated abscess drainage should be performed. However, if more than two drainage attempts have been made, consideration needs to be given to open operative drainage.^{2,18,20,46} Multiple abscess recurrence after successful evacuation of the abscess contents should prompt consideration of an

TABLE 72-3 Causes of Unsuccessful Drainage

	Cause
Causes due to catheter	Catheter blocked Catheter in improper position Small catheter for the collection Too few side holes in the catheter
Causes due to abscess	Multiloculated collection Presence of fistula, particularly enteric fistula Infection with fungal organisms Pancreatic origin

unsuspected diagnosis.^{18,20,46} The presence of fistula between the abscess cavity and another body cavity (bowel, biliary tree, or bladder) has a higher failure rate.^{18,20,46}

TIPS AND TRICKS TO IMPROVE OUTCOME

Catheter Blockage and Improper Position

A clogged or occluded catheter is often diagnosed when there is difficulty in flushing a catheter.³⁶ An occluded or clogged catheter needs to be exchanged for a new catheter for effective drainage.³⁶ However, before catheter exchange, a diagnostic imaging study, preferably CT, is necessary to confirm the position of the drainage catheter tip. Sometimes, the reason for ineffective drainage is abnormal position of the drainage catheter (Fig. 72-16).^{19,36} If the catheter is abnormally positioned or pulled out, repositioning and catheter rescue might be required.^{19,36} A new percutaneous drainage might be

Figure 72-16 Catheter dislodgment after percutaneous drainage. **A.** Axial CT image shows a left lower quadrant percutaneous drainage catheter placed in a 65-year-old man with diverticular abscess. The catheter tip is in the appropriate position within the abscess (arrow). The patient presented 2 weeks later with decreasing drainage from the catheter. **B.** Follow-up CT showed that the catheter had retracted from an intra-abdominal location into the subcutaneous tissues (arrow). The catheter was successfully repositioned into the abscess under fluoroscopic guidance.

Figure 72-17 Improved drainage of a perisplenic abscess after catheter exchange for a larger catheter with more side holes. **A.** Axial contrast-enhanced CT image in a 54-year-old man shows a large perisplenic abscess (arrows). **B.** Sagittal CT image shows persistent abscess despite adequate positioning of the catheter (arrows). **C.** Fluoroscopic image shows placement of a larger bore catheter with more side holes into the abscess over a guidewire (arrows). **D.** CT obtained 2 weeks later showed complete resolution of the abscess (arrow).

necessitated in situations in which catheter rescue is not possible and a substantial abscess cavity remains.^{19,36}

Increasing Catheter Drainage Surface Area

Percutaneous catheter exchange over a guidewire is the favored intervention for suboptimally drained abscesses despite adequate catheter placement.^{19,36} When postprocedure imaging

demonstrates reduction in abscess volume without significant resolution and appropriate positioning of the catheter within the collection, increasing the number of catheter side holes and increasing the catheter diameter improve drainage and have a higher rate of success^{19,36} (Fig. 72-17). Use of a longer drainage catheter with multiple side holes increases the drainage surface area, and therefore drainage of the abscess is more

effective.^{19,36} For example, a multi-side hole drainage catheter (e.g., 32-side hole biliary drainage catheter) provides better drainage than a five-side hole drainage catheter because of an increase in the number of side holes for drainage along the length of the catheter and decreased risk of catheter occlusion.¹⁹

Thrombolytic Agents

Certain abscesses are refractory to simple percutaneous drainage and benefit from instillation of thrombolytic agents, which improves percutaneous drainage, thereby avoiding surgical débridement.^{3,21,36,47} Thrombolytic therapy is particularly helpful in multiloculated abscesses or abscesses with extremely viscous contents that result in limited or no drainage from the catheter despite the presence of a large residual collection and proper catheter positioning. The difficulty in drainage is due to fibrin matrix deposition in the abscess, which causes loculations interfering with simple catheter drainage.^{3,21,36,47} The basic principle of the use of thrombolytic agents is their ability to cause fibrinolysis, which involves degradation of fibrin through activation of plasmin from plasminogen (Fig. 72-18). The fibrinolysis results in lysis of the septations and loculations, mobilizing abscess fluid.^{3,21,36,47} Thrombolytic agents such as tissue plasminogen activator (tPA) and urokinase also act to reduce the viscosity of abscess contents, thereby facilitating catheter drainage.^{3,21,36,47} It is a proven safe therapy for management of abscesses and is associated with only minimal risk of bleeding, even in patients who are receiving prophylactic anticoagulation.^{3,21,36,47}

At our institution, tPA is the preferred agent for thrombolytic therapy. The preferred dosage in our institution is 4 to 6 mg of tPA reconstituted in 50 mL of 0.9% saline per administration.^{21,47} The volume of instilled tPA is adjusted on the basis of the size of the cavity and usually should be 30% to 50% of the initial cavity volume.^{21,47} The reconstituted tPA is instilled into the abscess cavity, and the catheter is clamped for approximately 30 minutes to 1 hour.^{21,47} At the end of this period, the tube is opened to gravity drainage. We routinely administer six doses of tPA during a period of 3 days (two doses per day). After completion of the administration of tPA, diagnostic imaging with CT is performed to assess the efficacy of the thrombolytic therapy. Instillation of the thrombolytic agents early in the course of drainage therapy improves the likelihood of success compared with later instillation.^{3,21,36,47} The dosing of urokinase is 250,000 units reconstituted in 250 mL of sterile saline to achieve a concentration of 1000 U/mL and divided into three equal aliquots administered during a period of 24 hours.⁴⁸ After administration of each aliquot, the catheter is clamped for 30 minutes to 2 hours before the catheter is opened for gravity drainage.⁴⁸

Fungal Abscesses

Fungal abscesses are increasingly encountered in hospitalized patients, mostly in immunocompromised patients and elderly and intensive care unit patients.^{49,50} Although technically highly successful, percutaneous drainage of fungal abscesses has limited success because of the higher clinical failure rate.^{49,50} The most common fungal organism isolated from these abscesses is

Figure 72-18 Thrombolytic therapy for effective abscess drainage. **A.** Transverse ultrasound image of a 67-year-old man with an intraperitoneal abscess shows multiple internal septations (arrows). Percutaneous abscess drainage was performed. **B.** CT obtained 2 weeks later shows persistent abscess despite adequate catheter positioning (arrows). High density of the internal contents of the abscess suggests viscous contents. tPA instillation was performed into the abscess. **C.** CT obtained after six doses of tPA showed improved liquefaction of the abscess contents (arrows). **D.** Follow-up CT obtained 1 week later showed complete collapse of the abscess cavity (arrows).

Figure 72-19 Diverticular abscess with fistulous communication to sigmoid colon. **A.** Axial CT image shows a percutaneous drainage catheter within a diverticular abscess associated with sigmoid diverticulitis (arrows). The patient continued to have persistent drainage from the catheter for 4 weeks. **B.** Fluoroscopically guided injection of contrast material into the abscess cavity (thick arrow) showed fistulous communication of the abscess cavity with the sigmoid colon (thin arrows).

Candida albicans (79%), followed by *Candida glabrata*.^{49,50} Varghese and colleagues reported a technical success rate of 79% and a clinical success rate of 57% for percutaneous drainage of fungal abscesses. The predictors of poor clinical outcome in fungal abscess include presence of loculations at imaging, history of malignant disease, and admission to the intensive care unit.^{49,50} Drainage can be optimized in such situations by placement of larger bore catheters with larger diameter or catheters with an increased number of side holes.^{49,50}

Abscesses with Fistulous Communication

Intra-abdominal abscesses are often complicated by fistulous communication with surrounding structures within the abdomen, which can often impede effective drainage.* The risk factors for fistulous communication include abscesses developing in patients with Crohn's disease, diverticulitis, pancreatic duct injuries, and postoperative abscesses after bowel surgery.* The presence of a fistulous communication should be suspected in these patients during the management of their intra-abdominal abscesses. The diagnosis of fistulous communication is normally made during fluoroscopically guided injection of contrast material into the drainage catheter (Fig. 72-19).^{3,36} CT with positive oral contrast agents can also be performed to confirm the diagnosis in suspected fistulization to the bowel. The presence of a fistula is also indicated by the change in the nature and appearance of the drainage fluid. For example, the initial purulent drainage from an abscess transforms into fluid resembling origin from other body cavities, such as bile, bowel contents, urine, or pancreatic fluid.^{3,36} An additional sign that is highly suggestive of fistulous communication is a persistently high drain output from the catheter.^{3,36}

The management of an abscess with fistulous communication to other abdominal structures, particularly bowel, is complex and challenging. The presence of a fistulous communication usually necessitates prolonged catheter drainage because premature catheter removal results in abscess recurrence due to reaccumulation of fluid. Surgery remains the definitive treatment option in these patients. In patients who are poor surgical candidates, the management strategy often

involves prolonged catheter drainage for several weeks to months to allow healing and the fistula to close. In many situations in which the patient is unfit for surgical intervention, adjunctive procedures may facilitate fistula healing.^{18,20,29,36} For example, sphincterotomy with endoscopic biliary stent placement for biliary diversion is effective in patients with infected bilomas from biliary injury as this allows internal biliary drainage and curtails bile leakage into the abscess cavity, promoting healing.^{18,20,29,36} Similarly, in patients with infected urinomas caused by post-traumatic urine leaks, urinary diversion away from the urinoma can be achieved with a ureteral stent or a percutaneous nephrostomy catheter to aid closure of the fistula.^{18,20,29,36} In patients with high-output enteric fistula, prolonged parenteral nutrition and exclusion of oral nutrition may be necessary.^{18,20,29,36}

ABSCESSSES AT SPECIFIC LOCATIONS

Liver Abscess

Liver abscesses are often either pyogenic or amebic in origin.^{3,51-54} Other causes, such as fungal and protozoan, are uncommon. Pyogenic liver abscess most commonly occurs in the United States, whereas amebic liver abscesses account for most cases of hepatic abscess throughout the world.^{3,51-54} Hepatic abscesses cause significant morbidity and mortality despite advances in antibiotic therapy.^{3,51-54}

Pyogenic liver abscesses usually result from prior abdominal surgery, trauma, neoplastic disease, biliary tract disease, or bacteremia in immunocompromised patients.^{3,18,51-54} Intra-abdominal infections such as diverticulitis and appendicitis often result in hepatic abscess by bacteremia from the portal vein; however, their incidence has fallen because of improved management of these conditions with antibiotic therapy.^{3,18,51-54} Hepatic abscesses can also result from complications of prior hepatobiliary surgeries involving biliary-enteric anastomoses, liver transplantation, and locoregional therapies such as transarterial chemoembolization and percutaneous tumor ablation.^{3,18,51-54} In addition to features of abdominal sepsis, such as abdominal pain, fever, and chills, the patients with hepatic abscess present with leukocytosis and elevated bilirubin and alkaline phosphatase.^{3,18,51-54} Pyogenic abscesses can be single or multiple (46%-71%).¹⁸ *Klebsiella pneumoniae* is the most

*References 2, 9, 19, 20, 29, 36.

common microbe in solitary abscesses, whereas *Escherichia coli* is most often involved in multiple abscess groups.^{3,18,51-54} Single pyogenic abscesses are usually located in the right lobe of the liver, whereas multiple abscesses usually occur in both lobes.^{3,51-54} Untreated pyogenic abscesses are almost uniformly fatal.¹⁸ On ultrasound, pyogenic abscesses have a cystic or hypoechoic appearance with internal debris and often demonstrate posterior acoustic enhancement.¹⁸ Amebic abscesses are manifested as rounded or oval lesions with a homogeneous hypoechoic appearance without irregular walls as seen with pyogenic abscess.¹⁸ On CT, they are manifested as low-attenuation masses with a rim of peripheral enhancement surrounded by a hypodense halo due to surrounding edema.^{3,18}

The cardinal rule in the management of pyogenic liver abscess is early intervention with either surgical or percutaneous drainage and parenteral antibiotics.^{7,9,18,54-57} A single abscess can be drained by ultrasound, whereas multiple abscesses are drained with CT guidance (Fig. 72-20).⁷⁻⁹ Percutaneous drainage is effective in treatment of 70% to 94% of patients.^{7-9,18,53,58-60} Higher rates of morbidity and mortality are seen in patients with multiple or multiseptate abscesses and with underlying comorbidities, systemic sepsis, delayed diagnosis, or fungal superinfection.^{7-9,18,53,58-60}

Amebic liver abscesses are common worldwide and caused by *Entamoeba histolytica*.^{9,18,61} They are common in individuals living in or with history of recent travel to endemic areas and in immunocompromised individuals.^{9,18,61} Amebic liver abscesses are often single and seen in the right lobe of the liver in a subcapsular location.^{9,18,61} The cornerstone of therapy in patients with amebic liver abscess is medical management with metronidazole.^{9,57} The option of drainage is restricted to patients in whom medical therapy fails, to those with abscesses larger than 6 to 8 cm, and to those in whom there is increased risk of rupture.^{9,57,61,62} Amebic abscesses have a better response rate than pyogenic abscesses do.^{9,57,61,62}

Splenic Abscess

Splenic abscess is a rare condition with an incidence of less than 1%; however, an increasing number of cases are being reported in immunocompromised patients.^{3,18,63-66} Splenic abscesses most often result from metastatic hematogenous infections secondary to endocarditis, contiguous sites of infection, and

trauma.^{18,63-66} Splenic abscess can be associated with a high degree of morbidity and mortality because of the risk of sepsis and splenic rupture.^{3,18,63-66} Early diagnosis and intervention are imperative to improve outcome. Patients usually present with left upper quadrant pain, fever, and leukocytosis.^{3,18,63-66} Imaging has a high sensitivity in the diagnosis of splenic abscess ranging from 75% to 96%, with CT performing better than ultrasound.^{18,63-66} Percutaneous drainage of splenic abscess has success rates between 75% and 100% and is an effective treatment strategy for single lesions along with antibiotic therapy because it precludes splenectomy and preserves splenic function.^{3,18,63-66} In patients with multiple splenic abscesses, splenectomy might be the preferred option, except in patients with high risk for surgery.^{3,18,63-66} For percutaneous drainage, the subcostal approach is preferred to avoid traversing the pleural space, but the intercostal approach might be required because of the subphrenic location of the spleen.³ Multiloculations, septations, viscous contents, and abscess rupture with bleeding are considered to be relative contraindications to catheter drainage, and the surgical option is preferred.^{18,63-66}

Peripancreatic Abscess

Peripancreatic fluid collections, pancreatic pseudocysts, pancreatic abscess, and pancreatic necrosis are common findings in patients with acute pancreatitis.^{18,35,67-71} Percutaneous drainage of peripancreatic fluid collections and pseudocysts should be considered a treatment option when these collections become superinfected.^{18,35,67-71} Noninfected pancreatic pseudocysts or peripancreatic fluid collections can be observed conservatively, and percutaneous drainage may be indicated only in the presence of symptoms such as recurrent abdominal pain, mass effect causing biliary or bowel obstruction, intracystic hemorrhage, or increasing size of the collections.^{9,67,68,71,72} Superinfection is often suspected clinically, and contrast-enhanced CT scans can help in diagnosis.¹⁸ However, percutaneous aspiration with Gram stain and culture could be performed for confirmation before percutaneous drainage.^{3,34,35} Percutaneous drainage has reported cure rates of 65% to 90%, and surgical intervention is reserved for unresponsive collections.^{18,35,67-71} CT is preferred for percutaneous drainage of peripancreatic collections because they are often deep seated and have a complex anatomy (Fig. 72-21).^{18,35,67-71} Fluid collections or abscesses related to

Figure 72-20 Pyogenic hepatic abscess drained by percutaneous drainage. **A.** Contrast-enhanced axial CT image shows a peripherally enhancing air-containing abscess in the left hepatic lobe (arrows). **B.** Contrast-enhanced axial CT image 2 weeks after abscess drainage shows resolution of the left hepatic lobe abscess (arrow).

Figure 72-21 Percutaneous drainage of infected peripancreatic fluid collection. **A.** Contrast-enhanced axial CT image in a 45-year-old man with acute pancreatitis shows a large fluid collection adjacent to the pancreatic tail (arrows). **B.** Axial CT image after percutaneous drainage shows resolution of the peripancreatic abscess (arrows).

pancreatitis often result in catheter drainage for longer periods (weeks to months), particularly in collections with fistulous communications to bowel or pancreatic duct.^{3,19,67} Successful repeated percutaneous drainage is possible in some patients with fistulas.¹⁸

Pancreatic and peripancreatic necrosis may result in accumulations of material with fluid attenuation at CT. This necrotic material is viscous and often does not drain completely through the catheter.^{3,9,67,68,71,72} In suspected cases of infected pancreatic necrosis, needle aspiration can be performed for confirmation of infection.^{3,9,67,68,70-72} If the area of necrosis is not infected, the recommended treatment is supportive care.^{3,9,67,68,70-72} If the area becomes infected, surgery is indicated. Percutaneous drainage can be offered as a temporizing measure before surgical intervention in critically ill patients unfit for surgery.^{3,9,67,68,70-72} Large-bore catheters, such as 20F to 30F catheters, are often required for drainage of infected pseudocysts or infected pancreatic necrosis if significant debris is present or if the abscess contents are thick and viscous.^{18,35,67-71} Aggressive catheter management with irrigation is often helpful.³

Retroperitoneal Abscess

Abscesses in the retroperitoneum most often arise from the pancreas or are renal in origin. Renal abscesses are common in patients with preexisting renal diseases, such as nephrolithiasis, hydronephrosis, septicemia, and diabetes mellitus.¹⁸ Renal abscesses can be localized within the renal parenchyma or can rupture externally to be manifested as a perinephric abscess.¹⁸ If renal or perirenal abscess is associated with a urinary obstruction, a percutaneous nephrostomy is needed to relieve the obstruction and could also be used as an access for stone removal.¹⁸ Infected urinomas can also manifest as retroperitoneal abscesses. For infected urinomas resulting from post-traumatic urine leaks, urinary diversion through either a ureteral stent or percutaneous nephrostomy might be required to facilitate healing.^{18,20,29,36,73}

Abscesses in the iliopsoas compartment constitute an important entity and may develop secondary to previous surgery, penetrating trauma, hematogenous spread, contiguous spread from spinal osteomyelitis or tuberculosis, renal abscess, or inflammatory bowel disease.^{18,74} Abscesses in the iliopsoas compartment should preferably be drained under CT guidance because of their ability to demonstrate the location and extent of the abscess and its relationship to nearby structures.¹⁸

Pelvic Abscess

The pelvis is a frequent site of abscess formation, particularly in postoperative patients, because of its dependent location.¹⁸ The other common causes of pelvic abscesses include diverticulitis, appendicitis, Crohn's disease, postirradiation enteric fistulas, and pelvic inflammatory disease.^{3,18} Several safe approaches can be used for effective drainage of pelvic abscess, including the transgluteal, transvaginal, and transrectal route, as the presence of overlying bowel loops and bladder precludes a direct anterior or anterolateral approach.^{2,3,9,18,36} Sonographic guidance is used for drainage by the transvaginal or transrectal route, whereas CT guidance is used for transgluteal drainage.

In the transgluteal approach, the needle is directed caudal to the sacrospinous ligament, and it passes through the sciatic foramen (Fig. 72-22).^{2,25,40,75} To avoid transgression of sciatic nerves and superior and inferior gluteal vessels, the catheter must pass as close to the sacrum as possible while sparing the rectum.^{2,25,40,75} A common disadvantage of the transgluteal route is the significant discomfort and buttock pain.^{2,25,40}

The transvaginal approach provides the most direct access for drainage of abscesses situated close to the apex of the vaginal vault.^{2,76-78} The transvaginal approach is performed with an endoluminal ultrasound probe with a guide, which facilitates needle access for trocar-catheter insertion.^{2,76-78} However, this approach cannot be used for inaccessible collections in the presacral space or ischiorectal fossa.^{2,76-78} The transvaginal route is also not preferred for abscesses located high in the pelvis because of the risk of injury to urinary bladder, bowel, or vascular structures.² Technically, because the vagina is a muscular structure, puncture, dilation, and catheter placement may be difficult.^{2,76-78}

Enteric Abdominal Abscesses

Diverticular Abscess. Acute diverticulitis complicated by abscess formation is seen in nearly 25% of cases. Diverticular abscesses initially start as a microperforation at the site of inflammation with formation of a microabscess, which gradually grows in size to form a larger abscess.^{3,9,12,79} Without definitive treatment, these abscesses can potentially rupture, resulting in gross fecal peritonitis.^{3,9,12,79} Whereas acute diverticulitis is treated medically with antibiotics, development of abscess necessitates drainage either percutaneously or surgically.^{12,28,40} The role of percutaneous drainage in diverticular abscesses is

Figure 72-22 Transgluteal drainage of presacral abscess. **A.** Contrast-enhanced axial CT image shows a presacral abscess with an air-fluid level (arrows) in a 67-year-old patient with rectal cancer after rectal cancer surgery. **B.** CT-guided transgluteal drainage of the abscess was performed with placement of the catheter into the presacral abscess (arrows).

Figure 72-23 Percutaneous drainage of diverticular abscess. **A.** Contrast-enhanced CT image shows a large diverticular abscess (arrows) in a 51-year-old woman. **B.** Axial CT image obtained 2 weeks after percutaneous drainage shows complete collapse of the diverticular abscess cavity (arrows).

usually temporizing to relieve fever and other symptoms before definitive surgery, which involves resection of the affected segment of colon.^{3,12,28,40} Percutaneous drainage is primarily beneficial in cases with limited perforation without gross fecal spillage.^{3,12,28,40} Percutaneous drainage is effective in treatment of diverticular abscess with success rates of up to 90% and can decompress the abscess cavities well (Fig. 72-23).^{*} Percutaneous drainage combined with antibiotic therapy limits morbidity resulting from multistaged colonic surgeries for acute complicated diverticulitis.^{3,12,28,40}

Appendicular Abscess. Periappendiceal abscess may arise as a complication of acute appendicitis (preoperatively) or appendectomy (postoperatively) and is seen in up to 2% to 3% of cases (see Fig. 72-15).^{9,18,79,82,83} In patients with appendiceal rupture from acute perforated appendicitis, surgical drainage of periappendiceal abscesses has a high rate of morbidity.⁸⁴ Percutaneous drainage of the periappendiceal abscess as a temporizing measure allows the acute inflammation to subside, thereby limiting the degree of postoperative morbidity.^{9,18} In poor surgical candidates, percutaneous catheter drainage may be an alternative to surgery.³

Crohn's Disease. In patients with Crohn's disease, abscesses may occur either spontaneously or postoperatively.¹⁸ Abscess

formation in Crohn's disease patients can be multifactorial; causative factors include direct disease extension from an involved loop of bowel, hematogenous seeding, peritoneal contamination, and anastomotic breakdown after surgery.^{9,11,18,29,85} Abscesses most frequently occur between the leaves of the mesentery, between adjacent bowel loops, in the anterior peritoneum, in the right iliac fossa, in the retroperitoneum, or in the pelvis.¹⁸ Because of concurrent bowel involvement, intra-abdominal abscesses in Crohn's patients are often associated with fistula formation to the bowel, which is a predictor of the need for surgery.^{18,29} Percutaneous drainage of intra-abdominal abscesses in Crohn's patients often has a temporizing role before definite surgical intervention, given the relapsing chronic nature of the disease itself.^{11,18,29,85} Catheter drainage for several weeks is required in this group to allow fistulous communication with the bowel to heal.^{11,29,85} Fistulas tend to close on their own with bowel rest, parenteral nutrition, and long-term catheter drainage for healing.^{11,29,85} Success rates for percutaneous drainage are higher for postoperative abscess compared with spontaneous abscess.^{9,11,18,29,85}

Intraperitoneal Abscess

Infected intra-abdominal collections in the postoperative period are a common occurrence and often prolong hospital stay and increase morbidity and mortality. Early intervention and treatment are necessary in these patients because of the high mortality of up to 30% associated with postoperative intra-abdominal sepsis.^{5,18,86,87} Percutaneous catheter drainage is

*References 3, 12, 27, 28, 40, 80, 81.

the preferred treatment for management of postoperative abscesses because of the high morbidity associated with repeated surgeries.^{5,18} However, accurate diagnosis of a postoperative abscess is important to avoid drainage of noninfected inflammatory fluid collections. The diagnosis is rendered difficult in the immediate postoperative period because of fluid collections resulting from intraoperative irrigation, edema, old blood, and inflammatory changes.¹⁸ CT imaging is generally recommended on the eighth postoperative day for accurate characterization of intra-abdominal abscess.¹⁸ After recognition of intra-abdominal abscesses, percutaneous drainage is performed either as a definitive treatment or as a temporizing procedure before the surgical revision.¹⁸ The limiting factors for successful drainage of postoperative fluid collections include anastomotic dehiscence, multiple loculations, and increased viscosity of fluid contents.¹⁸ Abscesses at sites of enteric anastomoses often have fistulous communication to the bowel, which necessitates prolonged catheter drainage or corrective surgical intervention.¹⁸ At times, however, the anastomotic leak may heal and seal by percutaneous drainage alone.¹⁸

Intraperitoneal abscesses can also result from superinfection of preexisting fluid collections, such as hematomas, bilomas, urinomas, and even ascitic fluid, and these can be successfully treated by percutaneous drainage.³ Bilomas resulting from iatrogenic bile duct injury during hepatobiliary surgeries commonly have a persistent biliary fistula in more than 45% of cases.⁸⁸ To facilitate adequate healing, drainage of infected bilomas should be complemented by additional endoscopic or percutaneous procedures, such as biliary stent or percutaneous transhepatic biliary drain for biliary diversion away from the site of injury.^{3,88} Infected hematomas often do not drain well despite adequate liquefaction and might require the administration of thrombolytic agents such as tPA to improve drainage.^{3,21} Effective percutaneous drainage of infected large intraperitoneal fluid collections often necessitates placement of multiple catheters.^{3,8,39} The access route for drainage of a large intraperitoneal abscess is often straightforward and can be accomplished without difficulty by ultrasound or CT guidance.³ However, it is important to carefully select the percutaneous path for drainage to avoid vascular injury or bowel transgression.

Epigastric abscesses often result from hepatic, gastric, or colonic pathologic processes and have complex anatomic features because of their extent of involvement and proximity to several important structures.^{2,36} This necessitates use of CT guidance for safe percutaneous drainage of these complex abscesses, particularly for drainage of abscesses in the posterior epigastric region as they are surrounded by stomach anteriorly, liver and spleen laterally, and kidneys and bones posteriorly.³⁶ A transhepatic and transgastric route may be used that transgresses the periphery of the liver.³⁶

Subphrenic abscesses are manifested by their own unique challenges for percutaneous drainage because of their location and the necessity to transgress the pleura in most of the cases.^{2,36} Transgression of pleura can result in complications

such as pneumothorax, hemothorax, and conversion of a pleural effusion into an empyema.^{2,36} Left subphrenic abscesses usually develop after splenectomy, whereas a right subphrenic abscess may be related to liver trauma or liver surgery.^{2,36} Abscesses in the subphrenic location should ideally be drained through a subcostal approach to avoid the pleura, although an intercostal access may be necessary in the absence of a suitable subcostal window.^{2,36} In such circumstances, it is safer to be as caudal and anterior as possible with the drainage path to avoid the pleura because the anterior pleural reflection is cephalad compared with the posterior one.^{2,36} Combined ultrasound and fluoroscopic guidance is most suitable for drainage of a subphrenic abscess through the subcostal approach (see Fig. 72-13).^{2,36} In this procedure, a needle is initially placed through a subcostal route under ultrasound guidance into the most caudal aspect of the fluid collection. The needle is then used to manipulate a guidewire to a position beneath the diaphragm under fluoroscopic guidance. The guidewire access is then used to place a catheter into the subphrenic location by the Seldinger technique.^{2,36} Percutaneous drainage can also be performed under CT guidance, during which gantry angulation is used to place the catheter in the subphrenic location.^{2,36} Patients may complain of referred pain in the shoulder or scapular region during drainage of subphrenic abscesses, which usually resolves after drainage of the abscess.^{2,36}

Tumor Abscess

Tumor abscess is a rare occurrence and involves superinfection of a necrotic tumor.² In the majority of the cases, the diagnosis is straightforward as superadded infection develops in patients with a known malignant tumor.² A high degree of suspicion is warranted in other circumstances because abscess can develop in the postoperative bed after tumor resection.² Contrast-enhanced CT and MRI provide helpful clues to the diagnosis as they show irregularly enhancing solid areas within the abscess. The diagnosis of tumor abscess is crucial because percutaneous drainage in these cases should be avoided. Percutaneous drainage is not curative for tumor abscesses, and most often the catheters need to be in place indefinitely.² It can be performed in patients with sepsis or in those critically ill before definitive surgery. A frank discussion with the patient, the family, and the referring physicians is often necessary before percutaneous drainage of tumor abscesses to ensure appropriate education of the patient.²

Conclusion

Intra-abdominal abscesses have a high rate of morbidity and mortality if they are left untreated. Image-guided percutaneous drainage is a minimally invasive technique valuable in management of infected fluid collections. The intent of this chapter is to provide the radiologist with a bird's-eye view of percutaneous management of intra-abdominal abscesses to deal with both routine and challenging cases.

Gall Bladder and Biliary Tract

Gallbladder and Biliary Tract: Normal Anatomy and Examination Techniques

MARY ANN TURNER | ANN S. FULCHER

CHAPTER OUTLINE

Normal Anatomy

Gallbladder
Cystic Duct
Bile Ducts

Examination Techniques: Gallbladder

Plain Radiography
Ultrasound
Computed Tomography
Cholescintigraphy
Magnetic Resonance Imaging

Examination Techniques: Biliary Tract

Plain Radiography
Ultrasound
Computed Tomography
Computed Tomography Cholangiography
Magnetic Resonance Cholangiopancreatography
Direct Cholangiography
Biliary Scintigraphy

Rapid advances in technology and refinements in both noninvasive and invasive techniques have improved the ability of imaging methods to make more precise diagnoses in disorders of the biliary tract. Ultrasound and computed tomography (CT), because of wide availability and ease of performance as well as high diagnostic accuracy, are the first-line imaging techniques. Magnetic resonance cholangiopancreatography (MRCP) has assumed a larger role as a rapid, accurate, and noninvasive method of evaluating the bile ducts and has replaced diagnostic endoscopic retrograde cholangiopancreatography (ERCP) in most instances. Modern magnetic resonance (MR) and CT techniques including use of biliary-excreted contrast agents and postprocessing reformation methods, such as multiplanar reformation (MPR), maximum intensity projection (MIP), and volume rendering, allow detailed evaluation of the biliary tract with excellent accuracy and patient tolerance as well as three-dimensional data sets that can be cholangiographically displayed. Percutaneous transhepatic cholangiography (PTC) and ERCP are methods of direct cholangiography used for evaluation of biliary ductal disease. These techniques are invasive, but they are also safe and widely available. Improvements in the technical aspects of PTC and ERCP have led to the development of various interventional biliary procedures performed from both percutaneous and endoscopic routes. Plain radiography plays a minor role in imaging of the gallbladder and bile ducts. The traditional indications for operative and postoperative cholangiography remain unchanged; both techniques allow

direct opacification of the biliary tree but require surgical access and have limited diagnostic use. Biliary scintigraphy also has a limited role in biliary imaging, mainly for confirming acute cholecystitis and identifying bile leaks.¹⁻¹⁷

Normal Anatomy

GALLBLADDER

The gallbladder is an elliptical organ located in a fossa on the undersurface of the liver between the right and left lobes. Although size and shape vary, the relaxed gallbladder is approximately 10 cm long and 3 to 5 cm in diameter. Size may increase after vagotomy, in diabetes, or after cystic duct or common duct obstruction. Normal capacity is approximately 50 mL. The normal gallbladder wall is 2 to 3 mm thick, and the mucosa is composed of simple columnar epithelium. The gallbladder is usually apposed to the liver surface by parietal peritoneum. Rarely, the peritoneal reflection may be loose, forming a mesentery that allows the gallbladder enough mobility to extend into the pelvis or left abdomen, herniate into the lesser sac, or undergo torsion. The gallbladder is positioned partially or completely in an intrahepatic location in 10% of cases.

The gallbladder is divided into four parts—fundus, body, infundibulum, and neck (Fig. 73-1). The fundus is the rounded distal tip, which may project below the anterior inferior liver edge (Fig. 73-2). A characteristic deformity associated with septation and partial folding over of the gallbladder, the phrygian cap, may be found in the fundus. The body is the mid-portion of the gallbladder, which may be in contact with the duodenum and hepatic flexure. The infundibulum (Hartmann's pouch) is the focally enlarged segment between the body and the neck. The neck of the gallbladder lies between the body and the cystic duct and points toward the porta hepatis. A mucosal fold, the junctional fold, is frequently seen near the gallbladder neck. The gallbladder neck bears a constant relationship to the major interlobar fissure and undivided right portal vein or main portal vein, an important anatomic relationship for imaging.¹⁸⁻²⁵

CYSTIC DUCT

The gallbladder is attached to the common bile duct (CBD) by the cystic duct, which is usually 2 to 4 cm long and contains tortuous folds, the spiral valves of Heister (see Fig. 73-1). The cystic duct usually joins the common hepatic duct (CHD) from the right lateral aspect approximately halfway between the porta hepatis and the ampulla of Vater to form the CBD. The point at which the cystic duct joins the CHD is variable, from high in the upper extrahepatic bile duct or one of the intrahepatic ducts (more often the right) to low at the ampulla. The cystic duct

usually runs parallel to the CHD at least for a short distance and may insert either anteriorly or posteriorly or spiral around to insert on the medial aspect. The two ducts may have a long parallel course and can be encircled in a common connective tissue sheath²⁰⁻²³ (Fig. 73-3).

Figure 73-1 Normal anatomy of the gallbladder and cystic duct. (From Linder HH: *Clinical Anatomy*. East Norwalk, Ct: Appleton & Lange, 1989, p 421.)

BILE DUCTS

Intrahepatic Ducts

The liver is divided into right and left lobes on the basis of portal vein anatomy and biliary drainage. The right lobe is divided into anterior and posterior segments, and the left lobe is divided into medial and lateral segments by the fissure of the ligamentum teres. The bile ducts generally follow the internal hepatic segmental anatomy; however, marked variation in the branching pattern is common. Small branching interlobar bile ducts merge into larger ducts until the major left and right hepatic ducts are formed. A left medial segment duct and a left lateral segment duct normally join to form the main left hepatic duct. The right hepatic duct branches near its takeoff from the CHD. In approximately 60% of patients, the right hepatic duct has a dorsocaudal branch, with a characteristic hooklike configuration proximally, draining the posterior segment of the right lobe, and a ventrocranial branch, draining the anterior segment of the right lobe. Variations in the anatomic arrangement of the bifurcation branches are common, however, and it may be impossible to differentiate the anterior and posterior segmental branches on frontal cholangiograms. Common bifurcation variations include drainage of either anterior or posterior right lobe segmental ducts into the left hepatic duct, or a trifurcation configuration may occur. The left hepatic duct is more anterior and is usually longer and wider than the right hepatic duct. The left hepatic duct has a longer extrahepatic course and tends to dilate more with obstruction than the right

Figure 73-2 Normal anatomy of biliary tract. **A.** Frontal view. **B.** Parasagittal view.

hepatic duct does, presumably because there is less surrounding liver. Ductal drainage of the caudate lobe is variable and may be related to the left or right ductal system.¹⁸⁻²⁹

Extrahepatic Ducts

The right and left hepatic ducts emerge from the liver and unite to form the 3- to 4-cm-long CHD, which then joins the cystic duct to form the CBD. The union of the right and left main hepatic ducts is usually just outside the liver but may be lower, resulting in a shorter CHD or CBD. The CHD courses ventrally and inferiorly from the porta hepatis in the hepatoduodenal ligament accompanied by the portal vein, which lies posteriorly, and the hepatic artery, which lies medially. As the CHD passes inferiorly, it angles anteriorly and then posteriorly, crossing over the right portal vein and joining the cystic duct to form the CBD as it courses behind the postbulbar duodenum (see Fig. 73-1). The CBD averages 6 to 7 cm in length and is usually divided into suprapancreatic, intrapancreatic, and ampullary segments. In approximately 70% of patients, the distal CBD courses through the pancreatic head; in a smaller percentage, the CBD is located in a groove on the posterior surface of the pancreas. The CBD enters the posterior medial aspect of the

second portion of the duodenum through an oblique, 1- to 2-cm-long intramural tunnel terminating at the papilla of Vater.¹⁸⁻²⁴

The exact union of the CBD and the pancreatic duct at the ampulla varies. Most commonly, the two ducts join in the duodenal wall and have a short common channel (<5 mm). On occasion, separate orifices are present at the ampulla, or the ducts unite, forming a long common channel before entering the duodenal wall (Fig. 73-4). The sphincter of Oddi surrounds the common channel, and the choledochal sphincter (sphincter of Boyden) surrounds the CBD from its entrance into the duodenal wall to its junction with the pancreatic duct.³⁰⁻³² The extrahepatic ducts are sparse in muscle fibers (except in the cystic duct and the sphincter areas) and are composed primarily of elastic fibers. This allows relatively rapid change in size in response to fluctuations in intraductal pressure. With age, loss of elasticity may occur, resulting in enlargement of the duct, so-called ductomegaly of aging.³³⁻³⁶

Anatomic Variations

Anatomic variations and anomalies of bile duct anatomy are common (see Chapter 76). Although most are of no pathologic significance, an understanding of these variations is important to avoid misdiagnosis. Anatomic variations have been reported in 23% to 46% of cholangiograms, with the most common sites of involvement at the hepatic bifurcation and in the insertion of the cystic duct.³⁷ An aberrant right hepatic duct (4.6%) entering at a variety of locations (including low along the CHD or into the cystic duct), an accessory right hepatic duct (1.9%), and a high or low insertion of the cystic duct are congenital anomalies of significance because of the potential for injury at biliary surgery.^{20,22,24,25,37} (see Chapter 81).

Examination Techniques: Gallbladder

Modern gallbladder imaging involves primarily ultrasound and CT. Although the gallbladder is readily imaged by MR, this technique is less often used in gallbladder diagnosis because CT and ultrasound are accurate, quicker, less expensive, and easier to obtain. MR and MRCP, however, may be used as the initial imaging study in patients with suspected gallbladder carcinoma because of the greater ability to assess extent of disease and vascular involvement. Real-time sonography is the dominant screening method for the detection of gallbladder disease. Multidetector CT (MDCT) is commonly used to initially evaluate gallbladder disease, particularly neoplastic conditions and complicated cholecystitis, because of its ability to rapidly produce isotropic images of the upper abdomen.^{1-6,10,16,17}

Figure 73-3 Variations in cystic duct insertion.

Figure 73-4 Types of union of common bile duct and pancreatic duct.

PLAIN RADIOGRAPHY

Plain abdominal radiography is the simplest and least expensive imaging method that may identify gallbladder disease, but the yield is low, and this study is not used as a primary technique for assessment of suspected biliary or gallbladder disease. However, it is frequently the first study obtained in patients with upper abdominal pain, and gallbladder disease is occasionally apparent on the study. The normal gallbladder is not visible on plain radiographs. Only 10% to 15% of gallstones are sufficiently calcified to be visualized on the plain abdominal radiograph. “Porcelain” gallbladder, emphysematous cholecystitis, and milk of calcium bile (see Chapter 77) are other pathologic gallbladder conditions with characteristic findings that can be diagnosed on plain radiographs. A soft tissue mass in the right upper quadrant may be seen with hydrops of the gallbladder and gallbladder carcinoma.³⁸ Rarely, noncalcified cholesterol gallstones are visible on the abdominal radiograph as a result of nitrogen-containing clefts that produce a lucent, triradiate appearance, the “Mercedes-Benz” sign.³⁹

ULTRASOUND

Real-time sonography is the most widely used diagnostic study for the gallbladder and is the primary screening examination for gallbladder disease. The gallbladder is visible on sonograms in virtually all fasting patients despite body habitus or clinical condition. Gallbladder sonography is noninvasive, quick, and easy to perform. The examination can be performed portably and, because no ionizing radiation is used, is safe in pregnant and pediatric patients. Adjacent upper abdominal organs can be imaged simultaneously. The success rate of obtaining a diagnostic study is more than 95%.^{4,5,40-43}

By far the most common indication for gallbladder sonography is the detection of gallstones. Overall, the sensitivity, specificity, and accuracy of ultrasound for detection of gallstones is 95% to 99% in most series.^{4-6,10,40-43} The frequency of indeterminate studies with ultrasound is low.^{40,41} False-positive ultrasound findings are uncommon and are due primarily to polyps, folds, or cholesterosis of the gallbladder.⁴⁴ Although ultrasound is excellent for the demonstration of calculi, it does not provide direct information about gallbladder function or cystic duct patency. Sonography does have limitations in assessing the size and number of stones in cases of multiple stones. Sonography is useful to confirm the diagnosis of acute cholecystitis. Ultrasound has been shown to have a positive predictive value of 92% and a negative value of 95% for diagnosis of acute cholecystitis in patients with gallstones and a positive sonographic Murphy’s sign.⁴⁵ Complications of cholecystitis, including gallbladder perforation, gangrenous cholecystitis, and emphysematous cholecystitis, are usually readily seen by ultrasound. Gallbladder carcinoma, polyps, metastatic nodules, and adenomyomatosis are uncommon conditions of the gallbladder with characteristic findings on sonography^{4-6,42,43} (see Chapters 77 and 79).

Technique

The gallbladder is examined after the patient has fasted for at least 6 hours. This allows maximal distention of the gallbladder and enhances the detectability of stones. For most patients, real-time scanning is performed with a 3.5- or 4-MHz transducer. In thin patients or those with an anteriorly positioned

gallbladder, a 5-MHz transducer provides superior resolution. A transducer of the highest possible frequency should be used because spatial resolution is improved when the transducer focal zone is the same depth as the gallbladder.^{4,10,46} The examination is begun with the patient in the supine position. Scanning is performed in the right subcostal region or in one of the lower intercostal spaces, in approximately the anterior axillary line. The gallbladder is located in the longitudinal axis by identifying the major interlobar fissure of the liver (Fig. 73-5A). Views are obtained in the longitudinal and transverse planes to allow visualization of the entire gallbladder. Different degrees of inspiration may be necessary to move the gallbladder away from the overlying costal cartilage (Fig. 73-5B, C). Various scanning positions are used; decubitus positioning is often helpful in displaying the gallbladder, displacing bowel gas, unfolding kinks, and allowing small stones hidden in the neck to roll into the fundus to become detectable. The dependent portion of the gallbladder, particularly the neck, should be scrutinized for hidden stones (Fig. 73-5D). Suspended deep inspiration often serves to move the gallbladder into a more accessible position below the ribs. Magnified views, high-frequency transducers, and upright or Trendelenburg positioning are helpful adjuncts. Color Doppler sonography may be used in assessing cystic artery and wall flow in patients with acute cholecystitis or gangrenous cholecystitis and in evaluation of gallbladder carcinoma and metastatic disease to the gallbladder.⁴⁷⁻⁴⁹ If the gallbladder is not readily identified in its usual subhepatic position, other locations must be evaluated to exclude a positional anomaly. Examination of the gallbladder is always accompanied by evaluation of the bile ducts.

Normal Anatomy

The normal gallbladder in the fasting patient appears as an oval sonolucent structure with a thin (2-3 mm), uniformly smooth wall (see Fig. 73-5B, C). It is located by identifying the major interlobar fissure of the liver, which is apparent as a highly reflective line (because of periportal fat extending into the fissure)⁵⁰ (see Fig. 73-5A). The interlobar fissure is an important sonographic landmark because of its constant relationship to the gallbladder neck. Although gallbladder shape and size vary, the sonographic upper limits of normal size are approximately 8 to 10 cm in length and 4 to 5 cm in anterior-posterior diameter. Folds are commonly seen as echogenic foci adjacent to the wall. The junctional fold is a fold between the body and the infundibulum of the gallbladder, a common anatomic variant seen on sonography. If the gallbladder is not visualized by ultrasound, the most likely cause is prior resection or a scarred contracted gallbladder containing calculi. Agenesis of the gallbladder, calcification of the gallbladder wall, and intramural or intraluminal gas are other causes of nonvisualization⁵¹ (see Chapter 82).

COMPUTED TOMOGRAPHY

The gallbladder in fasting patients is nearly always identified on CT scans of the upper abdomen. Although gallstones are frequently visible, CT is not used as a primary examination for detection of gallstones because of its lower sensitivity (80%-85%) and higher cost compared with ultrasound.^{12,41,42,52-55} Calcified gallstones are manifested as high-density foci within the gallbladder lumen, and noncalcified stones are seen as low-attenuation filling defects within the surrounding bile. Although

Note the relationship of the gallbladder neck to the portal vein (pv, arrow) and common hepatic duct (chd, arrow). **C.** Transverse sonogram of the normal gallbladder (gb). Note the relationship to the liver (l) and the kidney (K). **D.** Sonogram shows a stone in a dependent position in the gallbladder (long arrow). A second stone behind the fold and impacted in the neck of the gallbladder (curved arrow) was seen only after careful evaluation of the neck in the erect position. Both stones cast characteristic acoustic shadows (short arrows).

acute cholecystitis is accurately evaluated with sonography or scintigraphy, CT is often used if the upper abdominal pain is nonspecific or if complicated cholecystitis is suspected. CT easily depicts mural thickening, gallbladder dilation, wall edema, septation, and increased bile density, which allows diagnosis. The main indication for CT in gallbladder disease is for the diagnosis and staging of gallbladder carcinoma (see Chapter 79) and evaluation of the complications of cholecystitis, such as perforation and pericholecystic abscess. Less common entities, such as porcelain gallbladder, milk of calcium bile, and emphysematous cholecystitis, are readily identified and have characteristic CT findings^{12,40-42,53,56,57} (see Chapter 77).

Technique

The gallbladder is usually scanned as part of a routine upper abdominal examination. Multislice CT scanning of the upper abdomen is performed during a single breath-hold after rapid bolus intravenous infusion of contrast material. This permits visualization of the gallbladder and optimal delineation of the gallbladder wall, intrahepatic biliary ducts, and extrahepatic bile duct by enhancing the contiguous liver and pancreatic parenchyma as well as blood vessels. Volumetric imaging with the latest generation scanners allows reconstruction in multiple

planes and different slice thicknesses. Images of 2- to 5-mm slice thickness are used routinely for review. Postprocessing with reconstruction of axial images at 1.5 to 3 mm can be performed and may be helpful in clarifying suspicious areas and in maximizing stone detection. Oral contrast material is routinely used in scanning the upper abdomen. However, in searching for smaller noncalcified stones, scans obtained without contrast material using thin sections filmed at narrow window settings optimize stone detection.^{55,57}

Normal Anatomy

The normal gallbladder on CT scans is a low-density, fluid-filled, elliptical structure in the interlobar fissure of the liver (Fig. 73-6A). A thin (2-3 mm) wall is often seen in normal patients and may show contrast enhancement. The gallbladder neck is superior and medial to the fundus. The gallbladder neck is often folded, and a portion may be cut in cross section. More caudally, the fundus of the gallbladder projects anteriorly and laterally and may touch the anterior abdominal wall or the colon. The duodenal sweep, hepatic flexure, and gastric antrum are contiguous structures (Fig. 73-6B-D). Significant variations in gallbladder size, shape, and position may be seen; however, the gallbladder neck maintains a constant position relative to

Figure 73-6 Normal gallbladder anatomy: CT. **A.** The gallbladder appears as a fluid-filled ovoid structure (arrows) in the interlobar fossa of the liver. **B-D.** Sequential CT scans show the normal position of the gallbladder (arrows) between the right and left lobes of the liver and the relationship of the gallbladder to the antrum (asterisk in **C** and **D**), duodenal bulb (d in **B** and **C**), and C-sweep of the duodenum (d').

the major interlobar fissure. The collapsed gallbladder may be more difficult to identify on CT scans.^{12,57}

CHOLESCINTIGRAPHY

Cholescintigraphy is used primarily for the diagnosis of acute cholecystitis; 3 to 5 mCi of technetium Tc 99m iminodiacetic acid (^{99m}Tc-IDA) compounds is injected intravenously, and the tracer is taken up by the liver and rapidly excreted into bile without undergoing conjugation, allowing visualization of the gallbladder and bile ducts (Fig. 73-7). Frequent anterior images are obtained up to 1 hour. Delayed imaging up to 4 hours and possibly 24 hours may be necessary in some instances. Nonfilling of the gallbladder on cholescintigraphy indicates functional obstruction of the cystic duct and is considered diagnostic of acute cholecystitis in the appropriate clinical setting. If the gallbladder fills, the cystic duct is deemed to be patent and acute cholecystitis is not present. This technique is highly sensitive and specific for the diagnosis of acute cholecystitis (95%-98%), and it is the procedure of choice to confirm the diagnosis.⁵⁸⁻⁶¹ Intravenous morphine sulfate and sincalide can assist gallbladder filling. Sincalide is a cholecystikinin analogue that produces gallbladder contraction and empties the gallbladder before the study, allowing the gallbladder to more readily fill with the tracer.

MAGNETIC RESONANCE IMAGING

The technology of MRI of the gallbladder and biliary ductal system has continued to evolve since the early 1990s. The gallbladder is routinely imaged on conventional MR studies of the liver and upper abdomen with T1- and T2-weighted sequences. Techniques for imaging of the gallbladder or bile ducts may be tailored to delineate either the wall of the gallbladder and bile ducts and the surrounding soft tissue or the biliary fluid within the lumen (see Chapter 75).

Imaging of the lumen requires optimal contrast between the biliary fluid and the surrounding tissues. Bright signal fluid techniques are generally used with heavily T2-weighted sequences to produce an MR cholangiopancreatogram. The development of MRCP has expanded the role of MRI as a non-invasive method to examine the biliary system. MRCP is performed with heavily T2-weighted sequences that depict fluid in the biliary ducts, pancreatic duct, and gallbladder as high signal intensity, whereas adjacent solid organs and flowing blood have little or no signal. The images produced resemble those of ERCP (Fig. 73-8). Although the primary goal of MRCP is to delineate the biliary and pancreatic ducts, incidental and intentional imaging of the gallbladder is possible even in the nonfasting patient. In many cases, the cystic duct and its site of insertion into the bile duct are also visualized. Although MRCP results in

Figure 73-7 Normal cholescintigram. Frontal view taken 30 minutes after injection of radioisotope shows normal visualization of the gallbladder (long arrow), bile ducts (short arrows), and bowel (curved arrow).

Figure 73-8 MRCP: normal gallbladder and bile duct. Heavily T2-weighted coronal image shows the gallbladder, hepatic confluence, and extrahepatic bile duct.

high-resolution images of the gallbladder, its role relative to ultrasound and CT for evaluation of gallbladder disease is limited primarily to problem solving, not to primary diagnosis, with the exception of gallbladder carcinoma. MR provides comprehensive imaging of the gallbladder and bile ducts as well as

of the surrounding structures, a feature most helpful in staging of tumors arising from or involving the gallbladder.^{12,16,62-66}

Technique

Conventional MRI of the gallbladder and bile ducts frequently combines the use of T1- and T2-weighted sequences. T1-weighted fat suppression sequences with and without intravenous gadolinium chelates may be helpful in demonstrating the lumen as well as the wall of the gallbladder and the bile ducts. T2-weighted sequences may be used in evaluating the surrounding soft tissues. Heavily T2-weighted MR sequences are used to perform MRCP. A number of sequences have been used since its introduction, including two-dimensional fast spin-echo and three-dimensional fast spin-echo. Technical refinements provided by the half-Fourier rapid acquisition with relaxation enhancement (RARE) sequence allow rapid imaging, such that the entire biliary tract can be imaged during an 18-second breath-hold.⁶⁴⁻⁶⁷ A typical MRCP examination comprises multiple acquisitions obtained at variable angles that optimally delineate the biliary tract and gallbladder. The half-Fourier RARE sequence minimizes magnetic susceptibility artifacts, such as those associated with surgical clips and bowel gas. A thin-slab, multislice technique is often used in both axial and coronal planes. From these source images, three-dimensional reconstructions may be generated with an MIP algorithm. No intravenous or oral contrast material is administered.

Normal Anatomy

On MRI, the gallbladder lumen can have a high or low signal intensity, depending on the chemical composition of bile and the pulse sequence used (Fig. 73-9). Concentrated bile is high signal intensity on T1- and T2-weighted images, whereas dilute bile is low in signal intensity on T1-weighted images because of its higher water content. Because concentrated bile has a greater specific gravity than dilute bile, concentrated bile settles in the dependent portion of the gallbladder. On MRCP, gallbladder calculi, regardless of composition, appear as low signal intensity filling defects within the high signal intensity bile (Fig. 73-10). Calculi as small as 2 mm can be identified. In addition to calculi, MRCP can depict neoplastic disease of the gallbladder and its extent. Adenomyosis of the gallbladder may be incidentally identified when the fluid-filled Rokitsky-Aschoff sinuses are seen within the gallbladder wall.^{16,62,64,66,68-71}

Examination Techniques: Biliary Tract

A number of examination techniques are available for evaluation of the biliary ducts. In selection of an imaging technique, several factors must be considered, including clinical presentation, diagnostic information desired, body habitus, and anatomic alterations from previous surgery. If direct cholangiography with PTC or ERCP is used, the potential for conversion to a therapeutic intervention must be considered.

Ultrasound and CT are frequently used as the primary non-invasive methods for screening of patients with suspected ductal disease, although MRCP is being used more often and is now considered the primary evaluation method of choice for biliary ductal disease. MRCP is noninvasive and can be performed rapidly, depicting the intrahepatic and extrahepatic bile ducts as well as the pancreatic duct and surrounding structures. Although CT cholangiography has been widely used in Europe and on a limited basis in the United States for ductal evaluation,

Figure 73-9 Normal gallbladder: MRI. **A.** T1-weighted fat suppression image shows high signal intensity, concentrated bile in the dependent portion of the gallbladder (arrow) and low signal intensity, less concentrated bile in the nondependent portion of the gallbladder (arrowhead). **B.** T2-weighted fat suppression image depicts bile in the gallbladder as high signal intensity.

Figure 73-10 Gallbladder calculi. MR cholangiogram shows multiple gallbladder calculi as multiple filling defects in high signal intensity bile. The extrahepatic bile duct (arrowhead) is noted.

this technique is rarely used in current practice. CT cholangiography provides information similar to that of MRCP but requires intravenous administration of a cholecystographic agent before the CT study. This technique has several limitations, including use of contrast agents with the associated risk of reaction, lack of ready availability of the contrast agents used, inconsistent opacification of the ducts from the contrast agents, and limited opacification of the ducts in patients with biliary obstruction.

Direct opacification of the bile ducts by PTC or ERCP can provide detailed information about ductal anatomy or pathologic changes; however, these are invasive procedures. PTC or ERCP may also serve as a preliminary step to

nonsurgical therapeutic interventions, such as biliary drainage, stent placement, stone removal, or stricture dilation. Biliary scintigraphy is occasionally useful in detection of bile leaks, evaluation of biliary enteric anastomoses, or diagnosis of early or segmental biliary obstruction. Operative cholangiography and postoperative cholangiography are standard methods to evaluate the bile ducts after surgical access to the ductal system. Plain radiography has a limited role and is rarely useful in defining bile duct disease.

PLAIN RADIOGRAPHY

The biliary ductal system is visible on plain radiographs only when it is outlined with air or calcification. Air in the biliary tree most commonly results from a surgically created biliary-enteric anastomosis. Erosion of a gallstone into the gastrointestinal tract and erosion of a peptic ulcer or tumor into the biliary tree are other causes of biliary-enteric fistula that may result in biliary air. Rarely, calcified stones in the bile ducts are visible on plain film.³⁸

ULTRASOUND

Evaluation of the bile ducts in search of stones, mass, or obstruction is one of the main applications for ultrasound. Real-time ultrasound readily depicts dilated biliary ducts, which in most instances is indicative of biliary obstruction. The extrahepatic bile duct can be seen in most patients regardless of body habitus or clinical condition. Because the bile duct is oval in cross section in the majority of patients, measurement of the transverse diameter on axial images correlates more closely with ductal diameters measured on ERCP.⁷² The CHD is the most easily visualized portion of the extrahepatic biliary system and can be rapidly visualized and measured in virtually all patients.^{1,4-9,73} Intrahepatic ducts are rarely seen unless they are dilated. The distal CBD may be obscured by gas in the duodenum. The primary goal of biliary sonography is the detection of dilated ducts because the size of the extrahepatic duct is a fairly sensitive indicator of the presence of biliary obstruction. Early changes of intrahepatic and extrahepatic ductal dilation are readily seen with ultrasound. Frequently, the lesion causing the biliary obstruction is identified as well.^{4,5,73} Ultrasound is an accurate and reliable technique to assess the intrahepatic and extrahepatic ducts as well as adjacent structures, such as the pancreas.

Technique

The bile ducts are best evaluated with high-resolution real-time equipment and the highest frequency transducer possible: 3.5 MHz in obese patients and 5 MHz in thin patients. Optimal imaging of the CHD and proximal CBD is obtained by parasagittal scanning with the patient in the supine left posterior oblique or left lateral decubitus position.⁷⁴ The CHD is identified as a tubular sonolucency anterior and lateral to the proximal main portal vein or the undivided right portal vein (Fig. 73-11A). The right hepatic artery passes between the posteriorly located portal vein and the anteriorly located CHD. In 10% to 15% of patients, the artery is anterior to the CHD. The standard measurement of the CHD is made at this level. The measurement is made from interior wall to interior wall perpendicular to the scan plane. Doppler sonography of the porta hepatis may be needed to distinguish the bile ducts from adjacent vascular structures.⁷⁵

The distal CBD is more difficult and frequently impossible to image because of overlying gas in the duodenum and hepatic flexure. Visualization can be improved by scanning with the patient in the semierect (60 degrees to the vertical) right posterior oblique position in the transverse rather than in the parasagittal plane⁷⁶ (Fig. 73-11B). This position minimizes antral and duodenal gas, allows fluid to enter the antrum and duodenum, and allows the left lobe of the liver to descend, creating an acoustic window. With this technique, the distal duct can be seen in up to 90% of cases.⁷⁷ The specific point of union of the CHD with the cystic duct is usually not seen.

After examination of the extrahepatic ductal system, the proximal ducts and intrahepatic ducts are examined with the patient in the supine or left posterior oblique position. The normal right and left main hepatic ducts can be visualized coursing anterior to the undivided right portal vein and the initial segment of the left portal vein, respectively.

Normal Anatomy

The normal intrahepatic ducts are less than 1 to 2 mm in diameter and are usually not visible. Although visualization

of intrahepatic ducts generally implies biliary dilation, larger central intrahepatic ducts can occasionally be visualized anterior to the portal veins in the right and left lobes near the porta hepatis in normal thin patients with use of a 5-MHz transducer. Gross intrahepatic duct dilation is easy to detect sonographically as the “parallel-channel” sign, formed by dilated intrahepatic ducts running anterior and parallel to the portal vein tributaries.^{1,2,4-7} Dilated intrahepatic ducts tend to have acoustic enhancement posteriorly, which distinguishes them from veins. The use of color Doppler is helpful to distinguish bile ducts from small hepatic vessels. This is especially so for the left lobe of the liver, where parallel branching hepatic anterior and portal veins may mimic dilated left intrahepatic ducts.⁷⁵

The normal CHD measures 4 to 5 mm or less on sonograms. The CBD measures 4 to 6 mm normally, with a 6- to 7-mm diameter considered equivocal. These measurements reflect the internal dimension of the duct. A diameter of more than 8 mm is indicative of ductal dilation.^{4-6,78-80} Sonographic measurements of duct size are smaller than those obtained by direct cholangiography because there is no radiographic magnification or distention resulting from injected contrast material.^{81,82} Some variation in extrahepatic ductal diameter may be due to elastic properties of the bile ducts, which can expand and contract rapidly during normal physiologic filling and emptying, with Valsalva maneuver, or with deep inspiration. There is controversy about whether extrahepatic ductal diameter increases with aging. In a study by Wu and coworkers³³ of 256 normal patients, the CBD size was shown to increase roughly 1 mm per decade after the age of 50 years, indicating that an apparently enlarged CBD may be seen in normal elderly patients. This study also suggested that the upper limit of normal may be up to 10 mm in the elderly population. Two additional studies, one with a cohort of 350 patients³⁶ and another with a cohort of 45 patients,³⁵ support these data. These findings, however, were refuted in a study by Horrow and colleagues³⁴ of 258 patients that did not confirm an association between age and size of the extrahepatic bile duct in an asymptomatic adult population.

Figure 73-11 Extrahepatic biliary anatomy: ultrasound. **A.** Sonographic demonstration of the common hepatic duct (chd, arrow) located anterior to the portal vein (pv). Note the gallbladder (gb) anteriorly. **B.** Normal distal common bile duct (cbd, arrow) is seen in the head of the pancreas on a semierect transverse sonogram. Pancreatic duct (pd, arrows) is also seen.

Ductal Diameter and Biliary Obstruction: Limitations

Sonography has an overall accuracy of more than 95% in the detection of dilated ducts and diagnosis of biliary obstruction.^{73,78,80,83} However, bile duct caliber does not always correlate with the presence or absence of biliary obstruction. Biliary obstruction without dilation may be seen in patients with low-grade or intermittent obstruction resulting from stricture or small stones and in patients with sclerosing cholangitis.^{84,85} Alternatively, dilated ducts may be seen in the absence of obstruction in patients with prior biliary surgery or patients with resolved obstruction.^{86,87} The decreased elasticity of a dilated duct may result in persistent dilation despite relief of the obstruction. Intestinal hypomotility, recent laparotomy, hyperalimentation, and prolonged fasting can cause ductal dilation presumably secondary to factors that inhibit relaxation of the sphincter of Oddi. An enlarged CBD may be seen in normal, unobstructed elderly patients.³³ Ultrasound is accurate in diagnosing the level of obstruction in 92% to 95% of cases and identifying the cause of obstruction in 70% to 88%.^{5,6,73,77}

Postcholecystectomy Dilation

Whether dilation of the duct occurs after cholecystectomy has been debated in the literature for years. It has been proposed that in the absence of a gallbladder, the CBD dilates to function as a reservoir. Two studies, however, suggest that if the CBD is normal before surgery, it generally remains so after surgery unless disease intervenes.^{78,88,89} A reassessment of the effect of cholecystectomy on duct size found that after cholecystectomy, most patients did not have significant compensatory dilation of the duct.^{79,89} Once a duct dilates, it may lose elastic recoil and never return to normal. Accordingly, some postcholecystectomy patients have biliary “dilation” but nonobstructed ducts. The maximal upper limit of the CBD allowed after cholecystectomy is 10 mm.⁴ The general recommendation is that further studies are warranted if the CHD measures 6 mm or greater in symptomatic patients.

Fatty Meal or Cholecystokinin Sonography

Administration of a fatty meal followed by sonography is an adjunctive maneuver that provides functional information, helps identify patients who require further evaluation with direct cholangiography, and increases the accuracy of ultrasound in detecting obstruction. This technique is helpful in postcholecystectomy patients with suspected obstruction in the absence of ductal dilation, in patients with equivocal duct size, and in asymptomatic patients with abnormal results of liver function studies suggesting occult obstruction. Magnified views of the CHD are obtained, and the internal diameter is measured at a fixed point. A fatty meal or intravenous cholecystokinin is administered, and another measurement of CHD caliber is obtained 30 to 45 minutes later if a fatty meal is used and 5 to 10 minutes later if cholecystokinin is used. A fatty meal and cholecystokinin cause gallbladder contraction, sphincter of Oddi relaxation, and increased bile flow. The normal, nonobstructed duct decreases in size or does not change in caliber. An increase in caliber—or, if the duct is initially dilated, a failure to decrease in caliber—suggests some degree of ductal obstruction and the need for further evaluation. A true change in ductal diameter occurs only if the size changes by 2 mm or more.^{58,90-92} Using these criteria, Simeone and colleagues⁹⁰ reported 84%

sensitivity for fatty meal sonography in predicting the presence or absence of CBD obstruction.

COMPUTED TOMOGRAPHY

Continued evolution of CT technology, including refinements of multidetector scanning technology, has enhanced the utility of CT for evaluation of biliary duct disease. With the use of high-resolution scanners and fine collimation, minimally dilated intrahepatic and extrahepatic ducts are now easily visible. Visualization of the entire CBD is routine on CT scans of the upper abdomen.^{2,93,94} Imaging is not inhibited by overlying gas. CT is more reliable than sonography in determining the caliber of intrahepatic and extrahepatic ducts. In addition, because of more complete delineation of the total length of the CBD, CT is also more useful than sonography for precisely defining the site and cause of biliary obstruction. Whereas ultrasound has been used to screen patients with biliary obstruction in the past, CT and MR are now the first-line diagnostic studies and are no longer used as a follow-up study after ultrasound to refine the data or to confirm anatomy.^{2,11,12,95} CT has an accuracy of 96% to 100% in detecting the presence of biliary obstruction, 90% in determining the level of obstruction, and 70% in identifying the cause of obstruction.^{2,94,96,97} The reported sensitivity of CT for detection of bile duct stones is 72% to 88%.⁹⁵ In addition, CT can often differentiate benign from malignant causes of obstruction and can provide guidance for biopsy and staging of malignant neoplasms.⁹⁸

Technique

Optimal CT scanning of the bile ducts requires rapid intravenous infusion of a bolus of contrast material combined with rapid scanning in the portal venous phase, usually 70 to 80 seconds after bolus injection of contrast material (100-150 mL). With current volumetric MDCT technology, the entire abdomen, with complete depiction of the intrahepatic and extrahepatic biliary tree, can be imaged in less than 5 seconds. MDCT scanners produce a volumetric data set that can be reconstructed in multiple dimensions for interpretation. Standard reconstruction includes 2- to 5-mm-thick axial images. High-quality multiplanar (MPR) coronal, coronal oblique, and curved planar reformatted images as well as three-dimensional reconstructions of the biliary ductal system may be helpful in defining complex anatomy or to map the ducts for planning of therapy. In cases of biliary obstruction, coronal reconstruction or three-dimensional reformations of the dilated bile ducts from data obtained during routine scanning can be produced successfully by taking advantage of the “negative” contrast effect of low-attenuation bile in dilated ducts relative to the adjacent enhanced visceral organs and vessels.*

In searching for CBD stones, scanning may be performed initially without oral or intravenous contrast material. Although dense contrast medium in the bowel has the potential to cause streak artifacts across the CBD, obscuring detail, such artifacts are rarely a problem with MDCT scanners. Duodenal contrast medium may obscure an impacted stone in the ampulla, and contrast medium in a perivaterian duodenal diverticulum can simulate a stone. Contrast enhancement of the vasa vasorum of the CBD wall may also mimic

choledocholithiasis. Reconstruction in thin slices of 1 to 2 mm or the use of coronal reconstructions may allow better demonstration of calculi.* Proper selection of the correct window width and level is necessary to optimize visualization of the CBD throughout its entire course from the porta hepatis to the intrapancreatic portion.

Multiphase imaging during late arterial and portal venous phase imaging may improve visualization of hypovascular tumors involving the bile ducts. Delayed imaging (10-20 minutes after administration of contrast material) has been shown to be helpful in diagnosis of cholangiocarcinoma. The tumor demonstrates increased retention of contrast material compared with the adjacent liver.^{103,104}

Normal Anatomy

On MDCT scans of the liver and upper abdomen, the CHD and CBD are usually visualized throughout their entire course (Fig. 73-12A-D). Visualization of intrahepatic ducts on CT has been considered evidence of biliary dilation and obstruction. However, with MDCT scanners, bolus contrast enhancement, and 2- to 5-mm-thick scans, visualization of normal intrahepatic ducts may be seen in 40% of normal individuals.¹⁰⁵ The average size of the normal intrahepatic ducts is 2 mm in the central liver and 1.8 mm in the periphery. Demonstration of intrahepatic bile ducts on CT scans does not necessarily indicate biliary obstruction; however, few normal intrahepatic ducts

should be seen. Truly dilated intrahepatic ducts are readily apparent and, when present, indicate biliary tract disease. Bile ducts appear as water-density tubular branching structures converging at the porta hepatis. The left and right hepatic bile ducts course through the porta hepatis and join to form the CHD lying anterior to the portal vein.^{3,73}

The CHD and CBD are usually visible within the hepatoduodenal ligament^{3,73,106,107} (see Fig. 73-12A). The proximal extrahepatic duct forms a fairly straight, thin-walled, low-density tube anterior lateral to the portal vein, angling toward the midline. A more transverse orientation is present in approximately 6% of normal persons and 18% of those with dilated ducts.¹⁰⁷ The distal CBD appears on cross section as a circular, low-density structure in the pancreatic head or in a groove posterior lateral to the pancreatic head (see Fig. 73-12B, D). Visibility of the normal CBD is increased by contrast enhancement of adjacent vascular structures, pancreas, and liver parenchyma. The normal CBD is seen on CT scans at least 50% of the time. However, this figure is higher with contrast-enhanced MDCT, especially when reconstructed thin-slice thickness (2-5 mm) images and coronal reconstructed images are used. In a study using optimal technique, the normal CHD and CBD were visualized in 66% and 82% of cases, respectively.^{73,108} The duct wall may be discerned separately with a mean thickness of 1 mm and a maximal thickness of 1.5 mm. Contrast enhancement of the duct wall may occur in normal patients and should not be confused with peripheral calcification or stone. An isolated finding of duct wall enhancement should not be considered abnormal, although it can occur in

*References 2, 53, 55, 57, 73, 94, 101, 102.

pancreatitis, choledocholithiasis, sclerosing cholangitis, and cholangiocarcinoma.

The normal CHD on CT is 3 to 6 mm in diameter. A CBD diameter of 7 to 8 mm is generally considered upper limit of normal, and 8 to 9 mm is considered dilated.^{95,108} Anterior-posterior measurements are most accurate because the oblique segment of the CHD, when it is measured transversely, may give an artifactually large diameter. Axial CT images of the extrahepatic duct show sequential low-density circles that gradually taper as the duct courses through the head of the pancreas. The level of obstruction corresponds to the transition from dilated to nondilated duct.

COMPUTED TOMOGRAPHY CHOLANGIOGRAPHY

CT cholangiography, obtained after intravenous administration of contrast material that is excreted in the bile, displays biliary ductal anatomy and pathologic changes similar to direct cholangiography. This technique has been used for the noninvasive detection of biliary anatomy and variations before laparoscopic cholecystectomy and in living donor candidates for right hepatic lobe transplantation.¹⁰⁹⁻¹¹² CT cholangiography has also been used for noninvasive detection of bile leaks and bile duct stones and for evaluation of suspected biliary obstruction.¹¹³⁻¹¹⁵ Most reported studies have used intravenous contrast material, meglumine iodipamide, which is the same agent used in the past for intravenous cholangiography. The agent is infused during 20 to 30 minutes, and scanning is performed 15 minutes after the end of the infusion.^{114,115}

After administration of the contrast material, multislice CT images are obtained. Three-dimensional images are reconstructed with MIP and volume rendered techniques (Fig. 73-13). CT cholangiography is not commonly used because of the increased reaction rate associated with intravenous biliary contrast agents, the increased study time necessitated by the administration of the contrast material, the lack of effectiveness

in patients with jaundice or elevated serum bilirubin concentration, and the increased utility of MRCP, which provides similar information more quickly and without the use of contrast agents.¹⁰⁹⁻¹¹⁵

MAGNETIC RESONANCE CHOLANGIOPANCREATOGRAPHY

MRCP uses heavily T2-weighted sequences to generate bright signal from fluid in the bile and pancreatic ducts, allowing delineation of the ducts from surrounding tissues. An image of the ducts similar to that of ERCP is produced. Since its introduction in 1991, MRCP has undergone a number of technical refinements that now allow rapid imaging of the biliary system with consistent visualization of the entire extrahepatic ducts and most of the intrahepatic ducts in 90% to 100% of patients with normal-caliber ducts (see Fig. 73-8). Dilated ducts proximal to an obstruction are well visualized in virtually 100% of cases. The diagnostic accuracy of MRCP is comparable to that of ERCP in the evaluation of choledocholithiasis, malignant obstruction, and anatomic variants of the biliary tract. Simultaneous evaluation of the pancreatic duct is also obtained. The usefulness and accuracy of MRCP have been established in the evaluation of choledocholithiasis, malignant obstruction, congenital anomalies, and postsurgical alterations of the biliary tract¹¹⁶⁻¹²⁶ (Fig. 73-14). The improved spatial resolution afforded by recent refinements in MRCP permits visualization of calculi as small as 2 mm. In addition, MRCP depicts not only the dilated ducts proximal to a stricture but also the stricture itself. MRCP is particularly advantageous in the evaluation of patients who have experienced failed or incomplete ERCP.¹²² MRCP has a reported sensitivity of 89% to 100% and specificity of 83% to 100% for the detection of calculi.¹²⁵ MRCP is now considered to be the diagnostic imaging test of choice in the evaluation of biliary ductal disease. The major disadvantage of MRCP is that it is purely diagnostic and does not provide an access for therapeutic intervention (see Chapter 75).

Technique

State-of-the-art MRCP can now be performed with both two-dimensional and three-dimensional heavily T2-weighted sequences, usually RARE (fast spin-echo or turbo spin-echo) techniques.¹²⁴ Variants include single-shot fast spin-echo (also known as half-Fourier acquisition single-shot turbo spin-echo; Siemens Medical Solutions, Malvern, Pa) and fast-recovery fast spin-echo.¹²⁴⁻¹²⁷ The heavily T2-weighted sequences depict the bile ducts as high signal intensity structures against the low signal intensity of the liver (see Fig. 73-8). MRCP offers several advantages over direct cholangiography in general and ERCP in particular in that it avoids the administration of contrast material and exposure to ionizing radiation. The risks of pancreatitis, sepsis, and perforation associated with ERCP are avoided because the examination is performed without instrumentation. Because MRCP is entirely noninvasive, the high cost of sedation and postsedation recovery is eliminated.

MRCP may be performed with a variety of techniques. The multislice technique involves the acquisition of multiple 3- to 5-mm-thick source images of the biliary tract, which may be obtained during breath-hold or shallow respiration.^{16,116,117} With this technique, the biliary tract is first localized by obtaining a thick-slab image in the coronal plane (Fig. 73-15A). The

middle third of the extrahepatic bile duct is localized, and a thick-slab axial image is obtained at this level (Fig. 73-15B). This axial image is used as a guide to prescribe the appropriate angles for optimal delineation of the bile ducts with thin-slab (3- to 5-mm) images in the coronal oblique plane (Fig. 73-15C, D). Although imaging is most often conducted in the coronal plane, axial images may prove useful in confirming suspected CBD stones. From the thin-slab source images, three-dimensional images may be generated with an MIP algorithm or with MPR techniques. An alternative MRCP technique is that of single-shot projection.^{62,125,127} With the projection technique, a single thick (30- to 70-mm) image is generated during a 2-second acquisition.

Technical advances, such as improvements in software and the use of phased array surface coils, have resulted in high-resolution images of the biliary tract that can be acquired during a single breath-hold. When rapid imaging is obtained during a breath-hold, artifacts resulting from respiratory excursion are eliminated. Although the breath-hold technique is recommended, high-quality MRCP images can be obtained in critically ill or ventilator-dependent patients who are not able to cooperate for a breath-hold. Whereas MRCP is a focused examination of the biliary tract, conventional MRI with T1- and T2-weighted sequences may show normal bile ducts as low

Figure 73-15 MR cholangiogram: technique. **A.** Coronal thick-slab (7-cm) MR cholangiogram with a localizer (*curved arrow*) placed at the level of the middle third of the extrahepatic bile duct demarcates the area through which an axial thick-slab image will be obtained. The pancreatic duct (*arrowhead*) is noted. **B.** Axial thick-slab (7-cm) MR cholangiogram obtained at the level of the middle third of the extrahepatic bile duct is used as a reference from which angles (*curved arrow*) are prescribed to obtain thin-slab images of the duct in the coronal oblique plane. The bile duct (*straight arrow*) and pancreatic duct (*arrowhead*) are shown. **C.** Coronal oblique thin-slab (5-cm) MR cholangiogram demonstrates the proximal extrahepatic bile duct (*arrow*) and the cystic duct remnant (*arrowhead*). **D.** Coronal oblique thin-slab (5-cm) MR cholangiogram image obtained posterior to **C** shows the distal bile duct (*arrow*) and the pancreatic duct (*arrowhead*).

signal intensity tubular structures on T1-weighted images and high signal intensity structures on T2-weighted images. Conventional MRI with T1- and T2-weighted sequences also provides complementary information about the adjacent hepatic and pancreatic parenchyma (Fig. 73-16).

Contrast-Enhanced Magnetic Resonance Cholangiography.

The use of intravenous contrast agents to enhance ductal visualization continues to be investigated. Paramagnetic or T1 relaxation-enhancing agents, which are substantially excreted in the bile, may be used to obtain bright signal delineation of the bile ducts. Gadobenate dimeglumine (Gd-BOPTA, Multi-Hance; Bracco Diagnostics, Princeton, NJ), gadoxetic acid disodium (gadoxetate disodium [Gd-EOB-DTPA], Eovist or Primovist; Bayer Healthcare, Leverkusen, Germany), and mangafodipir trisodium (Teslascan; Nycomed, Zurich, Switzerland; not available in the United States) are three such agents that result in contrast-enhanced high signal bile, permitting good visualization of the biliary tract. These agents shorten the T1 relaxation time of bile, resulting in high signal intensity bile at

T1-weighted imaging. Imaging is performed 15 to 90 minutes after intravenous injection. These agents have been used for anatomic mapping of bile ducts before living donor liver transplantation and for the detection of bile leaks after transplantation. Disadvantages include the need to wait for sufficient biliary excretion of the contrast agent, the need for intravenous access, and the potential risk of the contrast agents.^{12,128} It is uncertain whether these agents have any significant advantage over the inherent contrast and clear ductal delineation provided by the currently used heavily T2-weighted sequences of MRCP.

Normal Anatomy

Normal-caliber proximal intrahepatic bile ducts and the entire extrahepatic bile duct are routinely visualized at MRCP. The intrahepatic bile ducts are depicted as high signal intensity branching tubular structures against the low signal intensity background of the solid parenchymal organs. The intrahepatic bile ducts can be distinguished from the low signal portal veins, which contain rapidly flowing blood. The high signal extrahepatic bile duct is seen throughout its course from the porta

Figure 73-16 MR cholangiogram: enhanced three-dimensional technique. **A.** Three-dimensional MIP image from T2-weighted MRCP in a patient with obstruction and dilated ducts from pancreatic carcinoma better demonstrating detail of the dilated bile ducts. **B.** Slightly rotated view demonstrates distal bile duct and pancreatic duct junction to better advantage.

hepatitis to the duodenum and is distinguished from the lower signal intensity solid organs.^{16,62-64,66} On conventional MRI, the normal extrahepatic duct is seen in approximately 50% of cases. The CBD is more readily depicted on axial projections in its intrapancreatic portion on conventional MRI of the upper abdomen, whereas normal intrahepatic ducts are not usually seen.¹²⁴⁻¹²⁶

DIRECT CHOLANGIOGRAPHY

Despite the high accuracy of ultrasound, CT, and MRCP in biliary disease, direct cholangiography (PTC or ERCP) may be needed when findings on cross-sectional imaging are equivocal or discrepant or when a therapeutic intervention is needed. Direct cholangiography is used to verify the presence or absence of biliary obstruction and to more precisely define the site and cause of an obstructive lesion. Direct cholangiography has a more than 95% success rate in determining the site and a more than 90% success rate in determining the cause of biliary obstruction. Direct cholangiography should always be preceded by ultrasound, CT, or MRCP to reveal unusual anatomy, areas of segmental ductal obstruction, and intrahepatic or extrahepatic mass lesions that would alter the manner in which cholangiography is performed and interpreted. Direct cholangiography clearly delineates biliary anatomy, an essential factor in planning surgical, radiologic, or endoscopic therapy. With the large variety of endoscopic and radiologic therapeutic interventions now available, direct cholangiography often serves as a prelude to nonsurgical biliary interventional procedures^{7,15,128-132} (see Chapters 74 and 78). Direct cholangiography by PTC or ERCP for purely diagnostic purposes is rarely done, having been replaced in current clinical practice by noninvasive imaging, particularly MRCP.

Percutaneous Transhepatic Cholangiography Versus Endoscopic Retrograde Cholangiopancreatography

The choice of procedure for direct cholangiography depends on a number of factors: the clinical situation, the potential for therapeutic intervention, and the availability of a skilled endoscopist or radiologist.

Although there are many similarities in the information provided by antegrade (PTC) and retrograde (ERCP) cholangiography, the advantages and disadvantages of each procedure must be carefully weighed before a decision is made. Both methods provide high-quality images of the ducts and are capable of evaluating intrahepatic and extrahepatic stenoses, ductal dilation, filling defects, and leaks. Both procedures allow transformation of a diagnostic study to a variety of therapeutic maneuvers.

PTC is easier and quicker to perform and is less costly. It has a high success rate; dilated ducts are opacified in virtually 100% and nondilated ducts in 80% to 85% of patients^{129,131} (Fig. 73-17). The complication rate is low (3.4%), and the procedure is performed by the radiologist.^{133,134} Therapeutic transhepatic options after PTC require a higher skill level. These include biliary drainage; stone extraction, crushing, contact dissolution, laser fragmentation, and contact lithotripsy; stent placement; stricture dilation; and biopsy. ERCP is more time-consuming, more expensive, and more dependent on the skill of the endoscopist. The success rate for cannulation of the bile duct varies from 80% to 95%, depending on the experience of the endoscopist.^{14,132,135-139} ERCP offers the advantages of direct pancreatic duct visualization and inspection of the upper gastrointestinal tract and ampulla. The complication rate is comparable to that of PTC (3%-5%).¹⁴⁰⁻¹⁴³ Therapeutic options at ERCP include sphincterotomy for stone extraction or ampullary stenosis, biliary stent placement, and balloon dilation of strictures.^{132,144,145} The procedure is performed by the endoscopist using fluoroscopic monitoring and usually in conjunction with the radiologist.

ERCP is preferred for evaluation of patients with nondilated ducts or more distal lesions. It is the procedure of choice if a primary pancreatic process is suspected and opacification of the pancreatic duct is desired (Fig. 73-18). ERCP is also recommended for patients with bleeding disorders, for whom PTC may be risky. PTC is generally preferred in the evaluation of more proximal lesions involving the hepatic duct bifurcation, which may be difficult or impossible to delineate with a retrograde approach. PTC is recommended when endoscopy is not available or previous biliary enteric surgery has been performed. PTC is also used if ERCP fails, and vice versa.

A

Figure 73-17 PTC. **A.** Diagram depicts the PTC technique. Shaded area between the needles is the preferred region for needle insertion. The circular shaded area should be avoided. **B.** PTC outlines the normal biliary ductal system. Note the needle (arrow) with the tip cannulating the small peripheral intrahepatic biliary radicle. **C.** PTC with the needle (curved arrow) in place shows the obstructive lesion (straight arrows) of the common hepatic duct and dilated intrahepatic ducts from metastatic periportal adenopathy. (A from Kadir S: *Diagnostic Angiography*. Philadelphia, WB Saunders, 1986.)

B

C

The choice of diagnostic PTC or ERCP also depends on the therapeutic plan for the patient. If a CBD stone is suspected, ERCP should be used to perform a sphincterotomy and endoscopic stone extraction (see Chapters 74 and 78). If imaging studies indicate a lesion at the hepatic duct bifurcation, PTC is more likely to outline the extent of involvement, to show the presence of segmental occlusions, and to define drainage options.

Percutaneous Transhepatic Cholangiography

PTC is a widely used, successful, and safe method of directly opacifying the biliary ductal system. Its relative ease and safety are related to the use of a fine, 22-gauge, highly flexible Chiba or “skinny” needle, introduced by Okuda and associates in

1974.¹⁴⁶ The small caliber and flexibility of the needle decrease the likelihood of hepatic injury during respiratory motion and decrease procedure-related complications. The success of ductal opacification with PTC is virtually 100% for dilated ducts and 80% to 85% for nondilated ducts.^{15,130,132} The success rate is improved with an increased number of needle passes. Failure of the ducts to opacify during PTC should not be misinterpreted as absence of obstruction or dilated ducts; rather, it may indicate an inconclusive study.

The overall complication rate for PTC is 3.5%.^{15,134,135} The most common serious complications include sepsis (1.4%), bile leak (1.45%), and intraperitoneal hemorrhage (0.35%). Rare complications include pneumothorax, hepatic arteriovenous fistula, reactions to contrast material, and death (0.2%).^{15,132-135}

Figure 73-18 ERCP. **A.** Filling of a normal nondilated bile duct (arrow) and normal pancreatic duct (arrowheads). **B.** The bile duct and pancreatic duct are dilated as a result of a distal common bile duct stricture (arrow) and pancreatic duct stricture (arrowhead) in a patient with chronic pancreatitis.

There are no absolute contraindications to PTC except uncorrectable bleeding disorders. Ascites makes the procedure more difficult but is not an absolute contraindication.

Technique. Before the procedure, clotting studies are obtained, and any disorder should be corrected with fresh frozen plasma and platelets. Mild analgesia is provided. The patient should be well hydrated. Broad-spectrum antibiotics are routinely used; the data suggest that 80% of patients with biliary obstruction by CBD stones and 25% to 30% of patients with malignant obstruction may have infected bile, and sepsis is a potential risk.^{15,129,132} Positive organisms are usually *Escherichia coli* and *Klebsiella pneumoniae*. The procedure is performed under fluoroscopic guidance. A percutaneous transhepatic puncture is made with the skinny needle by a right midaxillary approach (see Fig. 73-17A). Alternatively, a left-sided subxiphoid approach can be used if cannulation of the left hepatic duct is desired. The needle is inserted into the liver during suspended respiration, and contrast material is injected as the needle is slowly withdrawn until a duct is opacified. More than one puncture may be necessary, and there is no limit to the number of passes as long as the patient tolerates the procedure.

After cannulation of an intrahepatic biliary radicle, contrast material is injected, outlining the biliary ductal system (see Fig. 73-17B). Images of the opacified biliary tree are obtained in the supine, both oblique, and, if necessary, upright projections. In the presence of obstruction, it may be necessary to tilt the table upright or to turn the patient to the left lateral decubitus position to allow contrast medium to fill the left hepatic ducts or to flow to the site of a distal obstruction. Overdistention of the ductal system can cause sepsis and should be avoided. Contrast material is heavier than bile and may not mix readily with viscid bile in an obstructed system. In the supine patient, the posteriorly positioned right hepatic ducts are dependent and tend to fill preferentially, and the left ductal system may fail to opacify. Turning the patient to the left posterior oblique or left lateral decubitus position facilitates filling of the left duct. Failure of the right hepatic ducts to fill in the supine position is abnormal

and suggests a lesion obstructing the right hepatic duct. Erect or partially upright views may be necessary for adequate filling of the CHD and distal CBD. Coned-down views of the ampulla region may be helpful in clarifying the cause of obstruction in this area. In cases of hepatic bifurcation obstruction or segmental occlusions, multiple passes may be necessary to map the extent of involvement and to determine operability and surgical approach to the lesion.

Transcholecystic Cholangiography

If the percutaneous transhepatic route is unsuccessful, transcholecystic cholangiography can be used to opacify the biliary tree when the gallbladder is present. The technique is simple and involves puncture of the gallbladder aided by ultrasonic guidance to place the needle directly into the gallbladder. Contrast material is then injected into the gallbladder to fill the bile ducts. This technique more easily opacifies the distal bile duct but gives inconsistent intrahepatic ductal opacification^{132,147-149} (see Chapter 78).

Endoscopic Retrograde Cholangiopancreatography

Endoscopic cannulation of the papilla of Vater was first described in the United States by McCune and coworkers in 1968.^{13,133} Advances in technique and improvement in design of the side-viewing endoscope since that time have made ERCP a reliable and safe procedure for evaluation of both the pancreatic and the bile ducts. The primary indications for its use in the biliary tract are extrahepatic biliary obstruction, investigation of unexplained upper abdominal pain in patients with previous cholecystectomy, evaluation of cholangitis, suspected bile duct injury by previous surgery, and choledocholithiasis.^{14,136,138} The performance, interpretation, and complications of this procedure are discussed in Chapter 74.

Normal Cholangiographic Anatomy

The main intrahepatic ducts as well as the cystic duct, CHD, and CBD are routinely opacified. Normal intrahepatic ducts measure 1 to 2 mm in diameter; however, the size is

dependent on technical factors such as injection pressure, runoff into the gallbladder, and geometric magnification during filming. Second- and third-order branches are usually seen. The normal intrahepatic ducts branch regularly and smoothly. The extrahepatic bile duct is a smooth-walled, tubular structure extending from the porta hepatis to the duodenum. Distally, the intramural segment may be slightly narrowed and should not be confused with stricture. When it is partially relaxed, the choledochal sphincter (sphincter of Boyden) can create a wavy or narrowed appearance that may be mistaken for ampullary stenosis or neoplasm.³¹ When it is contracted, its upper rounded border produces a pseudocalculus defect, mimicking an impacted stone.^{150,151} This pseudocalculus defect disappears spontaneously after intravenous injection of glucagon, which relaxes the sphincter (Fig. 73-19). Contrast material should flow freely from the CBD into the duodenum during normal cholangiography. Normally, no splaying or crowding of ducts, caliber irregularity, strictures, or filling defects are seen.

The mean ductal diameter on direct cholangiography is less than 8 mm, with 10 mm considered the upper limit of normal. Magnification and injection pressure account for some of the discrepancy between cholangiographic and ultrasonic measurements. Studies have demonstrated a caliber increase of up to 5 to 6 mm simply as a result of the ERCP procedure.¹⁵² Often, the normal common duct is quite small (<4 mm). The prepancreatic portion of the CBD tends to be the widest segment.

Operative and Postoperative Cholangiography

Operative Cholangiography. Operative cholangiography was first described by Mirizzi in 1932,¹⁵³ and since that time, it has been an important adjunct to biliary tract surgery. The procedure is done at the time of cholecystectomy to detect biliary stones and to determine the need for CBD exploration, a maneuver that substantially increases the time, morbidity, and mortality of gallbladder surgery.

Technique. The bile duct is opacified during operative cholangiography by insertion of a needle or cannula directly into the cystic duct or CBD and injection of contrast material. This technique can be used with open cholecystectomy or with laparoscopic cholecystectomy. However, the rate of successful cannulation and opacification of the ducts is lower with the laparoscopic approach. Common duct exploration is difficult by the laparoscopic approach and is rarely performed laparoscopically. During operative cholangiography, a small volume of contrast material (5-7 mL) is injected initially, followed by the first radiograph. A second radiograph is taken after an additional 5 to 7 mL of contrast material is injected. Because air bubbles can simulate stones, the injection system should be cleared of air. Most operative cholangiography is performed with digital fluoroscopy. A portable radiographic unit with either a fixed or a movable table grid may also be used. The patient should be rotated slightly to the right to project the duct away from the spine. If common duct exploration is necessary, a T tube (usually 12F to 16F) is placed

Figure 73-19 Postoperative cholangiogram. A. T-tube cholangiogram demonstrates pseudocalculus defect. Note meniscoid configuration (arrow) of the distal common bile duct from the contracted choledochal sphincter mimicking an impacted stone. **B.** Spot image taken during the same examination after intravenous administration of glucagon shows disappearance of the pseudocalculus defect after relaxation of the choledochal sphincter. **C.** Biliary tube cholangiogram after liver transplantation with duct-to-duct anastomosis demonstrates straight, small-caliber tube entering the cystic duct remnant of the donor duct (arrow). Injected contrast material outlines the ductal system, demonstrating mild narrowing at the duct-to-duct anastomosis (open arrow).

after the procedure and a completion cholangiogram is obtained before closing. The cholangiogram should be free of motion, grid lines, and superimposed tubes or instruments. Adequate exposure factors and proper collimation should be used.^{154,155} The study is considered suboptimal unless complete filling of the intrahepatic and extrahepatic ducts is accomplished (Fig. 73-20). Spasm of the sphincter occurs in as many as 25% of cases after CBD exploration.¹⁵⁶ This may be related to rapid or forceful contrast medium injection or surgical manipulation. Anesthetic agents, such as morphine sulfate and fentanyl citrate, are known to produce spasm.¹⁵⁷ If spasm is present, glucagon should be administered intravenously to relax the sphincter.¹⁵⁸

Postoperative Cholangiography. After common duct exploration for stone disease or after liver transplantation with biliary ductal anastomosis, a surgically placed biliary catheter or T tube is usually left in the extrahepatic bile duct to allow ductal decompression and to provide access for postoperative cholangiography. Postoperative cholangiograms are obtained through the indwelling biliary tube. In the case of stone disease, a T tube is usually left in place and the study is performed 5 to 10 days after surgery to check for retained stones or fragments. If none are identified, the T tube is removed. If stones are present, they may be removed endoscopically or radiologically after maturation of the T-tube track (see Chapter 78). In the case of liver transplantation, a small-caliber biliary tube is left in place for a longer time, usually 2 to 6 months, and cholangiography may be performed at any time to assess the status of the bile ducts and the anastomosis.

Figure 73-20 Operative cholangiogram. Note the cannula in the cystic duct remnant with filling of the bile duct. There is a retained distal common bile duct stone (arrow).

Contrast medium is administered by hand injection or by gravity drip infusion under fluoroscopic monitoring. Because of the risk of bacteremia, some authors recommend coverage with antibiotics.^{11,154,155} Antibiotics are routinely administered before postoperative cholangiography in patients after liver transplantation. During cholangiography, both the intrahepatic and extrahepatic ducts should be opacified. Use of the upright or tilted position may be necessary to fill the distal CBD. Also, bubbles rise in the upright position, whereas stones gravitate into the distal duct. The Trendelenburg position facilitates intrahepatic ductal filling, and placement of the patient in the left posterior oblique or left lateral decubitus position helps opacify the left ducts. Oblique views minimize superimposition of intrahepatic branches. The optimal study is free of air bubbles, with adequate filling of the intrahepatic and extrahepatic biliary tree. Air bubbles may mimic stones but are usually differentiated by a smooth, round appearance and a tendency to cluster. Sphincter of Oddi spasm is relieved by increased injection pressure or the use of glucagon^{154,155} (see Fig. 73-19).

The accepted radiographic technique for this examination includes low kilovolts peak (70-75 kVp) exposures and dilute contrast material (10%-15% iodine). This technique frequently necessitates a long exposure time (2-4 seconds) to ensure good radiographic quality. The use of high kilovolts peak (100-110 kVp) exposures and full-strength contrast material (30%-38% iodine) has been advocated to improve overall film quality with less motion, to enhance stone detectability, and to decrease radiation to the patient and personnel.¹⁵⁹

BILIARY SCINTIGRAPHY

Although it is used primarily to diagnose acute cholecystitis, biliary scintigraphy has several applications in the evaluation of biliary ductal disease. It is a noninvasive method of evaluating biliary drainage and segmental obstruction and can assess patency or bile leak after cholecystectomy or biliary enteric anastomoses^{8,59,61} (Fig. 73-21). Biliary

Figure 73-21 Biliary scintigraphy. This study demonstrates bile leak along the right upper quadrant drain (arrows) from a choledochojejunal anastomosis.

scintigraphy may also play a role in evaluating early biliary obstruction when ultrasound results are indeterminate and do not correspond to clinical or laboratory parameters.¹⁶⁰⁻¹⁶² Other uses for scintigraphic evaluation of the biliary tract

include noninvasive evaluation of sphincter of Oddi dysfunction, assessment of bile duct injury and duodenogastric reflux, and evaluation for congenital biliary anomalies.^{59,163,164}

Complications of Endoscopic Retrograde Cholangiopancreatography

Since the implementation of endoscopic retrograde cholangiopancreatography (ERCP) into clinical practice in the late 1960s, ERCP has allowed exquisite display of the biliary tract and the pancreatic duct systems. The ducts were displayed with great spatial and contrast resolution; however, the ductal findings at times were also used as surrogates for parenchymal or local anatomic abnormalities.

Much of this information is now rightly being obtained non-invasively by the continued development of ultrasound, multi-detector computed tomography (MDCT), and especially magnetic resonance imaging (MRI) and magnetic resonance cholangiopancreatography (MRCP). However, the ERCP examination has continued to change as well, now providing critical advancements in endoscopic therapeutic uses. The continued important presence of ERCP in clinical practice still demands radiology expertise for the interpretation of the findings of this examination.

Technique

Communication between the gastroenterologist and radiologist is critical, for both patient care and medical-legal reasons. With both services usually on busy schedules and frequently being physically separated, the radiologist can obtain information through the dedicated imaging technologist associated with the examination, closed-circuit television, and the gastroenterologist's dictation from the electronic medical record system.

The examination should begin with an image centered over the patient's right upper quadrant even before the patient is endoscoped. This image will allow the gastrointestinal service to appreciate any radiopaque material that might obscure ERCP imaging. This image will also display any calcifications related to the pancreatic and biliary systems that might be covered up

with the injected 150 to 300 mg iodine/mL concentration of contrast medium that is typically used to opacify either system. This image and subsequent images are best obtained at 90 to 100 kVp, depending on the patient's size. However, the fluoroscopic and imaging techniques are frequently adjusted automatically by the fluoroscopic unit.

The duct system is ideally imaged with the cannula placed initially at the level of the sphincter. However, the gastroenterologist will frequently feel more comfortable with the cannula advanced into the duct system for better purchase. Relatively slow injection rate with sequential imaging documentation is most useful for the interpreting radiologist. For example, biliary tract stones tend to congregate distally. A deep cannulation and rapid injection of contrast material can make display of these filling defects difficult.

The patient is typically placed in the prone oblique position for this examination. This results in flowing of the relatively heavier contrast agent away from the cannula, coursing "upstream." With the injection, admixture artifacts may develop both at the cannula tip and at the site of inflow from the cystic duct into the biliary tract.

Also, because of the patient's prone position, the left hepatic duct system will fill before the right. If the right duct system fills first, as is usual for T-tube cholangiography, in which the patient is typically supine, careful examination for left-sided obstruction is needed. A normal cystic duct and gallbladder should be filled during this examination. Images of early filling of the gallbladder may demonstrate the relatively heavy contrast agent's beginning to outline the dependent gallstones in the gallbladder if it is present.

Imaging in multiple projections can be helpful in laying out normal or any abnormal anatomy. An attempt should be made to identify all of the central intrahepatic bile ducts. Lateral positioning of the patient can be helpful in distinguishing right from left ducts. In this position, the more anterior ducts belong to the left system (Fig. 74-1).

Finally, delayed images can be helpful. Allowing some of the contrast agent to flow out of the duct system, greatly facilitated by supine positioning, can bring out findings lost in the dense contrast. Delayed imaging can also help confirm obstruction even if the ducts themselves do not appear to be dilated. A normal pancreatic duct should be drained of contrast material within 10 minutes from injection; the biliary tract, without a gallbladder, should take no more than 45 minutes.¹

Anatomy

BILIARY TRACT

The biliary tract can be divided into the intrahepatic and extrahepatic systems. The intrahepatic biliary tract follows

Figure 74-1 Schematic of the biliary tract. A view from the lateral projection, with the patient prone, demonstrates that the left intrahepatic biliary tract (light gray) will fill before the right intrahepatic duct system (dark gray). Also in the prone position, injected contrast medium will flow away from the sphincteric segment because of the gentle downward course of the extrahepatic biliary tract.

the arterial blood supply of the liver draining the eight hepatic segments. There is, however, moderate variability in the intrahepatic duct network; for example, the duct draining the right posterior segment is frequently aberrant (Fig. 74-2). The intrahepatic ducts should appear smooth and gently taper as they course peripherally. The angles formed by these branches should be acute. Changes resulting in pruning of peripheral ducts, stiffening of the duct system, or deviation of the “flowing” appearance of this duct network should raise concern.

The extrahepatic ductal system actually begins with the right and left hepatic ducts, both of which have components outside the liver. The union of these two duct segments forms the common hepatic duct (CHD), which is approximately 2 to 4 cm in length.

The cystic duct joins the CHD at an acute angle, typically on the CHD’s right side. The cystic duct insertion may be anomalous. It may insert abnormally upstream in the CHD or even into the right posterior intrahepatic duct (see Fig. 74-2). It may also join the extrahepatic duct very distally or medially (Fig. 74-3). This variant anatomy can lead to anatomic confusion and possible surgical mishap, or it may predispose to the development of complications, such as the Mirizzi syndrome.

The common bile duct (CBD) is formed with the union of the cystic duct and CHD. This 10-cm duct segment courses caudally and gently anteriorly when the patient is in the usual prone position during the ERCP examination (see Fig. 74-1).

Figure 74-2 Bile duct aberrancy. The duct serving the right posterior hepatic segment is the most common anomalous intrahepatic biliary tree duct segment. A post-liver transplantation T-tube cholangiogram shows the right posterior duct (straight arrow) exiting below the bifurcation (arrowhead), in this case consisting of the right anterior segment and the left hepatic duct. Also note that the transplant’s cystic duct (curved arrow) originates from this aberrant duct.

Figure 74-3 Aberrant cystic duct. A magnified view of the distal common duct shows the cystic duct (arrow) originating medially from the intrapancreatic portion of the extrahepatic biliary tree. This anatomy is important to identify, alerting the surgeon before possible laparoscopic cholecystectomy. Numerous faceted gallstones are present in both the cystic and common ducts.

The combined CHD and CBD segments may be referred to as the common duct or extrahepatic biliary tree.

The distal CBD courses into the duodenal wall and into the major duodenal papilla, also named the papilla of Vater. This distal segment is usually smooth, but it may appear finely pleated or may contain a small diverticulum.

The distal CBD is usually met distally by the main pancreatic duct (MPD), the union of which forms a common channel, also known as the ampulla of Vater, of variable length (Fig. 74-4A). In approximately 10% to 20% of cases, each duct system enters the papilla and drains into the duodenum separately. This common channel varies in length from 2 to 15 mm but averages 5 mm.^{2,3}

These two ductal systems are wrapped in smooth muscle called the sphincter of Oddi (Fig. 74-4B), measuring 5 to 15 mm in length.⁴ This muscle segment has a constant, tonic basal pressure on which interval phasic contractions of approximately two or three times per minute are superimposed. These contractions can be appreciated at fluoroscopy during injection of contrast material. This phasic contraction can squeeze the ductal segments together to create the convex-upward

appearance of a stone. This so-called pseudocalculus sign is reversed with the contraction's end (Fig. 74-5).

The diameter of the biliary tract should be measured at the CBD. Most authors suggest a maximal diameter, corrected for magnification with the known 12-mm-diameter of the therapeutic endoscope, to be less than 12 mm.^{1,3} With age, presumably related to degeneration of the duct's elastic fiber network, the CBD may increase in diameter, resulting in a "floppy duct." The normal CBD diameter of ERCP imaging will be greater than that of ultrasound, CT, and MRI, most likely related to the combination of active injection of contrast material and duct relaxation produced by conscious sedation used at ERCP.

PANCREATIC DUCT

The length of the MPD varies from 10 to 25 cm,^{5,6} but it averages 16 to 17 cm.⁷ It typically has an S-shaped configuration (Fig. 74-6). The "toe" of the S courses horizontally from the sphincter, then ascends cranially. This segment drains the pancreatic head. The MPD then again turns into a horizontal

Figure 74-4 Sphincter segment anatomy. **A.** A schematic demonstrates the three types of duct unions: the Y type, with a relatively long common channel; a short common channel, leading to a V appearance; and, in a minority of cases, the two ducts enter the papilla separately in a U appearance. CBD, Common bile duct; PD, pancreatic duct. **B.** An abnormally long and ectatic channel is seen in this ERCP image. The sphincter is contracted (arrowhead), but the common channel (arrow) extends beyond the muscle wrap, allowing direct communication of the two duct systems. This is thought to be the anatomic origin of choledochal cyst development.

Figure 74-5 The pseudocalculus appearance. **A.** The initial ERCP image is obtained with the sphincter contracted, causing the appearance of an impacted stone. **B.** Seconds later, the sphincter relaxes, showing the normal, patent duct systems.

Figure 74-6 Normal ERCP appearance. The main pancreatic duct has an S-shaped appearance, gently tapering as it courses from the head to the tail. In this particular patient, the normal side branches are homogeneously gracile in appearance.

direction corresponding to the “shoulder,” running anterior to the superior mesenteric artery and its vein. The transition from the ascending to the horizontal segment is designated the neck. The remainder of the pancreas is divided between the body and the tail, either with the left side of the spine being the transition point or by simply dividing the duct from the neck to the end of the tail in half.⁸

The neck of the MPD may have a subtle, circumferential narrowing without upstream dilation. This normal variant is thought to represent the union of the embryonic dorsal and ventral ducts. Toward the upstream segment of the MPD, there is often bifurcation of the duct as it nears its termination. Anatomically, the tail is proximal and the head is considered distal, although some use upstream to describe anatomy toward the tail and downstream to refer to the anatomy coursing toward the pancreatic head.

The MPD results from the union of the embryologic ventral duct, Wirsung, and the dorsal duct, Santorini. The MPD has a smooth, gentle narrowing from the head to the tail. The maximum diameter, again magnification corrected, at the head is less than 6 mm.³ The ERCP normal values will again be less than those related to ultrasound, CT, and MRI. With age, the MPD may normally develop a more “stiff” appearance with some subtle ductal irregularity.

There is no “normal” side branch appearance on ERCP. Side branches may have a fine, slender appearance (Fig. 74-6), or

they may be wider in diameter. However, a given patient’s side branches should be uniform in appearance and should have a smooth, gentle tapering configuration as they head into the pancreatic parenchyma. Display of the side branch system, as well as of the MPD, to assess for various abnormalities is infrequent in today’s practice with the other imaging methods now available and because the risk of producing pancreatitis is relatively great with MPD injection.

Biliary Tract Neoplasia

Malignant neoplasms involving the biliary tract, both intrahepatic and extrahepatic, usually are manifested as stricture disease and less commonly as filling defects. The strictured biliary tract segment can be the result of direct mural involvement by the tumor or of compression or infiltration from adjacent diseased lymph nodes or hepatic parenchymal tumor. Unfortunately, benign disease involving the biliary tract also frequently results in a strictured appearance (Box 74-1). The different causes of the biliary stricture must be differentiated for appropriate management.

Morphologic appearance can be of some help in this differentiation. Malignant strictures tend to be long (≥ 1.5 cm), have an irregular, eccentric mural surface, and have a short (< 1 cm) transitional zone with a nodular or shouldered appearance.⁹⁻¹² The addition of contrast-enhanced MDCT or MRI can add criteria for a malignant appearance with increasing mural thickness, irregularity of the external mural border, and mural enhancement.^{12,13}

The cholangiographic appearance in identifying a malignant stricture is only approximately 70% to 85% for sensitivity, specificity, positive predictive value, and accuracy,⁹ so the added benefit of tissue sampling at ERCP can be important. Cells and tissue can be acquired by various methods: aspirated bile for cytology, brush cytology, fine-needle aspiration of the stricture for cytology, endobiliary forceps biopsy, and even analysis of material clinging to a retrieved plastic stent. Multiple types of acquisition methods will increase return. The sensitivity of either brush cytology or biopsy is approximately 56%, but their combined use improves the return to 73%.¹⁴ It has now been reported that the previous practice of sampling after stricture dilation does not increase the return on sampling.¹⁵ These results can be compared with the use of fine-needle aspiration at endoscopic ultrasound (EUS), which has a high return, at

least 80%, for distal malignant strictures from pancreatic cancer or cholangiocarcinoma.¹⁵

Endoscopic techniques are also useful for stent placement in lower duct malignant strictures. The clinical views of what type of stent to use and when to use stents in malignant strictures are continuing to evolve.^{14,16,17}

Pancreatic cancer is the most common cause of malignant biliary tract obstruction. Cholangiocarcinoma and gallbladder cancer are the most common primary bile duct tumors.¹⁰ A group of four different types of tumors, including pancreatic cancer and distal cholangiocarcinoma, can occur at the ampullary site to also cause bile duct obstruction, called periampullary tumors. Metastatic disease also is a common cause of malignant biliary tract obstruction, with gastrointestinal tract tumors, hepatocellular carcinoma, and lymphoma being common causes.

Pancreatic cancer involvement of the biliary tract is usually seen in the distal CBD segment, the intrapancreatic portion of the CBD (Fig. 74-7A, B). The length of bile duct stricture depends on both the tumor size within the pancreatic head and the nearness of the bile duct to the tumor's center. The transition of the strictured segment is usually rapid, with a nodular or shouldered appearance. However, as discussed before, pancreatic carcinoma can involve the proximal extrahepatic biliary tree from adjacent peribiliary lymph node involvement, and it

can also involve the intrahepatic ducts if there is hepatic metastatic disease (Fig. 74-7C, D).

Cholangiocarcinoma can be intrahepatic or extrahepatic in location. It is classified into one of three types: mass forming, periductal infiltrating, and intraductal growth. The mass-forming type of cholangiocarcinoma arises from small intrahepatic ducts. The carcinoma forms a hepatic parenchymal mass; MDCT and MRI are the most appropriate modalities for its detection and assessment for extent of disease. Cholangiography does not play a significant role in imaging.

The tumor associated with the periductal infiltrating cholangiocarcinoma grows within the wall of the biliary tract, causing mural thickening with an irregular (Fig. 74-8A) or smooth (Fig. 74-8B) stricture. It spreads in a submucosal manner and tends to infiltrate the periductal anatomy. This tumor frequently begins in the hilar region, where it is referred to as a Klatskin tumor. The tumor can grow upstream or downstream. Unfortunately, it also tends to extend into the periductal and perineural tissues as well as into the lymphatics, where MDCT or MRI may better define the extramural disease. ERCP does have a place if resection is anticipated (Fig. 74-8C). Cholangiography can be used to better define the biliary tract anatomy involvement by the Bismuth classification (Fig. 74-9). The Bismuth classification is used to evaluate proximal biliary tract resection of strictures or obstructions of various causes. ERCP can provide important information about the local anatomy through its exquisite spatial display of the duct system.¹⁶

At ERCP, the early periductal infiltrating type of cholangiocarcinoma can be manifested as a relatively short, smooth appearance to simulate a benign stricture.¹⁸ However, because cholangiocarcinoma is usually appreciated later in the disease process, this stricture tends to be longer and more irregular in appearance.

The much less common type of cholangiocarcinoma, the intraductal growing type (also referred to as papillary cholangiocarcinoma), is the most likely type of cholangiocarcinoma to be manifested relatively early in its course. It tends to spread superficially and not invade the bile duct wall. It has a better prognosis compared with the other types of cholangiocarcinoma.¹⁹ At ERCP, this tumor may be a well-defined, smooth, intraluminal papillary protrusion (see Fig. 74-8C); but there can be multiple papillary projections, and some of these papillary projections may have an irregular surface. The intraductal growing type of cholangiocarcinoma may cause obstruction of the upstream ductal system without clear definition of the tumor itself. This type of cholangiocarcinoma can also produce mucin to cause biliary dilation. There is a complex relationship between the intraductal growing type of cholangiocarcinoma, biliary papilloma or papillomatosis (Fig. 74-10), and intraductal papillary mucinous neoplasm of the bile duct (Fig. 74-11), all of which can be seen as a papillary projection on cholangiography.^{18,19}

Gallbladder carcinoma is the other primary biliary tract malignant neoplasm. Local disease from this primary may spread to the mid or proximal extrahepatic biliary tree by direct extension along the cystic duct, by lymphatics, or by enlarged peribiliary lymph nodes. The stricture may extend to the hilar bifurcation or into the right or left hepatic duct system. The intrahepatic ducts may also be compromised by the cancer's predilection to invade the adjacent hepatic parenchyma or from metastatic deposits within the liver, which can displace, infiltrate, or obstruct the intrahepatic duct system.

Figure 74-7 Biliary tract strictures from pancreatic carcinoma. **A.** The pancreatic cancer causes a rapid transition to a tight stricture in the intrapancreatic portion of the bile duct with marked upstream dilation. **B.** In this case, the pancreatic cancer has a longer bile duct stricture that is irregular in appearance (arrow). There is also a long diffuse narrowing of the pancreatic cancer in the adjacent main pancreatic duct (arrowhead). There is dilation of the upstream main pancreatic duct. There is also nodular effacement of the gas-filled duodenum from the pancreatic cancer. **C.** In a different patient, the proximal extrahepatic biliary tree (arrows) and intrahepatic bile ducts (arrowheads) are narrowed by metastatic disease to hilar lymph nodes and hepatic metastatic disease, respectively. **D.** The corresponding CT section demonstrates the pancreatic tail primary (T), metastatic hilar lymph nodes (arrow), and hepatic metastases (asterisks).

Figure 74-8 Cholangiocarcinoma appearances at ERCP. **A.** This periductal infiltrating cholangiocarcinoma demonstrates marked mural irregularity and stricturing of the common hepatic duct leading into the hilum. **B.** Another appearance of the periductal infiltrating cholangiocarcinoma demonstrates a long, smooth stricture. **C.** This intraductal growing type of cholangiocarcinoma has both a papillary component (*thick arrow*) and also a moderate amount of mural irregularity and narrowing compatible with superficial spread (*arrowheads*). There is also involvement at the bifurcation and intrahepatic ducts (*thin arrows*), which did not allow curative surgery.

Figure 74-9 Schematic of the Bismuth classification. A type I configuration represents occurrence of the stricture 2 cm or more from the common hepatic duct bifurcation. A type II configuration has less than 2 cm of normal duct before the bifurcation. The type III configuration leaves only the bifurcation intact. Type IV has narrowing of the bifurcation. Type V refers to injury of aberrant branches of the biliary tree. (From Taylor AJ, Bohorfoush AG III: *Interpretation of ERCP*. Philadelphia, Lippincott-Raven, 1997.)

At ERCP, the cystic duct may not fill or only partially fill. The mid to proximal duct can be splayed, be diffusely narrowed, or demonstrate an irregular stricture (Fig. 74-12). Some mass effect, stricture, or obstruction can also be related to enlarged hepatobiliary lymph nodes.

Distal CBD obstruction, and potentially downstream MPD obstruction, can be caused by a variety of tumors that can occur at the papilla of Vater. Because of the difficulty in imaging, endoscopy, surgery, and even histology to separate these tumors, these tumors are combined under the heading of periampullary tumors. These tumors can be either benign or malignant. Benign tumors in this area are less common and include the ampullary adenoma, local geographic benign tumors, and carcinoid.²⁰

Periampullary cancer refers to cancers from one of four structures: the pancreatic head, distal bile duct, duodenum, and ampulla. There are other, rare malignant neoplasms that can occur here as well, such as metastatic disease and lymphoma.²⁰ Even though these cancers share a similar location and clinical presentation, the underlying histologic type can dictate prognosis. The ampullary and duodenal cancers have the best prognosis, whereas the distal bile duct and pancreatic cancers have the worst.

Figure 74-10 Biliary papillomatosis. The multiple papillary projections protruding into the extrahepatic biliary tree are compatible with papillomatosis.

Although some authors suggest that contrast-enhanced MDCT with three-dimensional reconstruction is the preoperative imaging examination of choice for the periampullary tumor, CT can have difficulty in both the visualization and the accurate assessment of local disease.²¹ Biliary or pancreatic duct dilation may be visualized but the underlying tumor not appreciated.

ERCP can be of great help by directly visualizing the periampullary tumor at the time of endoscopy and display the possible intraductal involvement of the tumor during ductal injection of contrast material (Fig. 74-13). Tissue retrieval can also be obtained as well as stenting, if necessary, and even local endoscopic resection in the appropriate case.²⁰ However, EUS and even transpapillary intraductal ultrasound are frequently used by endoscopists for better assessment of local tissue

Figure 74-11 Intraductal papillary mucinous neoplasm of the biliary tract. **A.** Initial injection demonstrates an irregular filling defect in the common hepatic duct. This was a jellylike material with strands of contrast medium visualized in its interstices. **B.** After removal of this viscid material with a retrieval balloon, the left hepatic ducts and the common hepatic duct are now widely patent. There was no papillary tumor visualized.

involvement and possible local lymph node spread.²⁰ EUS can also be used for fine-needle aspiration of the tumor for histologic diagnosis. A periampullary tumor may not have an intraluminal component. The cholangiogram or pancreatogram may demonstrate only a narrowing without an intraluminal mass. In these cases, tissue retrieval is critical.

There are also less common malignant neoplasms that can affect the biliary tree. Hepatocellular carcinoma can affect the biliary tract by hepatic parenchyma compression, enlarged hilar lymph nodes, or rarely intraluminal growth. Metastatic disease may cause narrowing by hepatic parenchymal or lymph node extrinsic compression (see Fig. 74-7C, D), but it can also have direct mural involvement and possibly intraluminal growth (Fig. 74-14). Lymphoma can affect the intrahepatic or the extrahepatic bile duct. Lymphoma tends to displace and narrow but not invade the duct system (Fig. 74-15). It also tends to have relatively less obstruction for the degree of narrowing. Biliary cystadenoma or cystadenocarcinoma is an unusual tumor, typically seen in the middle-aged woman, that can splay the biliary tract or rarely have an intraductal component.

A final neoplasm of the biliary tract is the granular cell tumor. This is a submucosal, neurogenic tumor that typically is manifested in a young to middle-aged African American woman. When it is visualized at ERCP, it is a smooth, polypoid, or possibly annular-appearing stricture. It is important to raise the possibility of this tumor in this specific patient demographic because the tumor is benign in nature (Fig. 74-16).

Biliary Tract Infection and Inflammation

There are numerous causes of infectious and inflammatory biliary tract disease (see Box 74-1). The various infectious and inflammatory processes usually are manifested as a stricture. Typically, it is a combination of clinical history (i.e., patient

demographic, significant past medical history, and certain specific laboratory values) and imaging features that suggests the correct diagnosis.

The postoperative biliary tract stricture is by far the most common inflammatory stricture.²² Most of these strictures are related to laparoscopic cholecystectomy. Approximately 0.3% to 0.6% of surgeries result in biliary stricture.^{23,24} Although the duct compromise may be appreciated at the time of surgery or soon thereafter, the stricture may take weeks or years to be manifested. Although MRI and MRCP are now the imaging examinations of choice to assess for these delayed stricture presentations,²⁵ ERCP can help display and treat this injury.

The postoperative stricture is typically short and smooth and is located at the extrahepatic biliary tree at the site of the cystic duct takeoff or above (Fig. 74-17). Treatment of the stricture will depend on the type and complexity of injury, timing of discovery of the injury, and position of the stricture within the biliary tract. However, endoscopic treatment with dilation and plastic stent placement can be effective in establishing and maintaining duct patency.²⁶

Another major area of postoperative bile duct complication is in the post-liver transplantation patient. These complications consist of biliary tract obstruction, stricture formation, filling defects, sphincter of Oddi dysfunction, leaks, and necrosis. A varied rate of 5% to 32% is reported for bile duct complications in this patient population, ranking only second to rejection as the most common problem in this population.^{27,28}

Whereas MRCP has a place in imaging of this patient population,²⁹⁻³¹ ERCP continues to play a critical role in management and diagnosis. The better spatial resolution and the possible interventional therapies provided by ERCP are advantages over the noninvasive MRCP. Also, at times, bile duct obstruction is not reflected in biliary tract dilation (Fig. 74-18).^{17,28} ERCP will be needed to accurately assess for obstruction in these cases. Obversely, bile duct dilation can be present without obstruction, which can also be confusing at MRCP.

Figure 74-12 Gallbladder carcinoma. **A.** In this case, the gallbladder carcinoma produces an irregular mass effect on the common hepatic duct compatible with invasion (arrow). The cystic duct fills only minimally. A right intrahepatic duct (arrowhead) is splayed and narrowed by the intrahepatic involvement of the gallbladder cancer. **B.** The gallbladder cancer in this case displaces the proximal and mid extrahepatic biliary tree from right to left, but there is no significant narrowing. The cystic duct did not fill during this examination. **C.** A long, moderately severe, smooth narrowing with mild bowing of the common hepatic duct is present in this gallbladder cancer patient. A small segment of the cystic duct does fill in this case.

Biliary strictures account for just less than half of all post-liver transplantation biliary complications.³² These strictures are divided into anastomotic and nonanastomotic. The non-anastomotic strictures are typically longer, multiple, and intrahepatic. They are usually related to a macroangiopathic or microangiopathic etiology or immunogenic (e.g., recurrent disease, such as primary sclerosing cholangitis) in origin.³² Treatment for this type of stricture formation is more difficult and less successful with endoscopic or percutaneous approaches. The presence of these strictures frequently heralds the eventual loss of the transplant liver.

The anastomotic stricture is a short, focal narrowing at the surgical anastomosis (see Fig. 74-18). This stricture has a fibrotic component and is more amenable to endoscopic dilation and

plastic stent placement. The common edematous band at the anastomotic site seen within the first 2 weeks of surgery should not be mistaken for a true stricture. This band will usually spontaneously resolve but may rarely require a temporary plastic stent without balloon dilation for treatment.³²

The filling defects in the post-liver transplantation patient can be related to stones, biliary casts, blood clots, or debris and sludge. These intraluminal filling defects can usually be removed endoscopically. The possible underlying causes of these filling defects, such as stricture, bacterial infection, or ischemia, also need to be ruled out.^{26,32}

Although the etiology is poorly understood, sphincter of Oddi dysfunction accounts for approximately 2% to 3.5% of post-transplantation complications.³³ Bile duct dilation can be

Figure 74-13 Perampullary tumors. **A.** In this case of ampullary carcinoma, nodular filling defects are seen in both the common bile duct and main pancreatic duct. Forceps biopsy confirmed the diagnosis. **B.** In another case, a perampullary duodenal villous adenoma can be visualized from its relief within the duodenal gas (arrow). This patient presented with recurrent bouts of acute pancreatitis without biliary symptoms. **C.** No definite mass is seen at ERCP in this patient with an ampullary tumor. There is only the rounded configuration of a very distal common bile duct obstruction.

Figure 74-14 Metastatic disease and the biliary tract. **A.** In this patient with partial hepatectomy for metastatic colon cancer, the colon cancer recurrence has grown intraluminally. Colon cancer is a fairly common cause of intraductal growth. **B.** Cervical cancer metastatic disease not only obstructs the hilum by enlarged lymphadenopathy (arrowhead) but also has metastatic deposits directly to the gallbladder wall (arrows).

Figure 74-15 Lymphoma of the biliary tract. The long, smooth, common duct narrowing is caused by extrinsic mass effect from adjacent lymphoma.

seen in the donor or recipient duct system. Endoscopic sphincterotomy is appropriate therapy if this is clinically significant.

Post-liver transplantation biliary leaks usually occur at a cystic duct stump, the T-tube insertion site, or the anastomotic site. These leaks are readily treated with sphincterotomy or plastic stent placement. If the leak is related to ischemia, endoscopic treatment will not provide adequate treatment.²⁶

Biliary strictures can be associated with chronic pancreatitis. These strictures are present in the intrapancreatic portion of the CBD, being caused by the surrounding pancreatic fibrosis and occasionally a combination of fibrosis superimposed with edematous change from acute pancreatitis. The biliary tree can also be narrowed by an adjacent pseudocyst in this patient population.

Approximately 25% of chronic pancreatitis patients will develop a stricture in the intrapancreatic segment,³⁴ although the incidence varies from 3% to 46%.³⁵ The recurrent acute

Figure 74-16 ERCP in this young woman with incidental elevated liver function test results demonstrates a smooth, submucosal/extrinsic-appearing common bile duct narrowing. A granular cell tumor was found at surgery.

inflammatory attacks lead to increasing fibrosis in the pancreas that includes the periductal parenchyma. Not all such narrowings need to be treated, but clinical correlation is needed to make sure that the untreated stricture does not result in one of the potential complications of bile duct narrowing: secondary biliary cirrhosis, ascending cholangitis, or choledocholithiasis.^{34,36} For the relatively unusual bile duct stricture that requires treatment, endoscopic dilation with multiple plastic stent placements can be tried. With increasing fibrotic change in the surrounding pancreas, this endoscopic approach can be less effective.^{34,37,38}

The biliary tract stricture in chronic pancreatitis typically has an hourglass appearance of the long, smooth stricture in the distal CBD (Fig. 74-19A). There are various appearances of bile duct stricture in chronic pancreatitis,³⁵ with one series suggesting that up to one third of the bile duct strictures related to chronic pancreatitis had a more aggressive appearance with a short, abruptly narrowing stricture and even shouldering to cause significant upstream dilation³⁹ (Fig. 74-19B).

Figure 74-17 This postoperative stricture (arrow) is approximately 1 year after laparoscopic cholecystectomy. This stricture is very short and smooth and located at the common hepatic duct bifurcation.

Choledocholithiasis is another common entity causing obstruction and possible infection. Most of these ductal stones are secondary, that is, they migrate from the gallbladder into the extrahepatic biliary tree. Anywhere from 5% to 18% of cholecystectomy patients will have choledocholithiasis.⁴⁰

“Primary” stones may also develop, causing choledocholithiasis. These stones originate within the lumen of the bile duct itself. These are typically calcium bilirubinate stones seen in patients with increased red blood cell breakdown, alcoholic patients, senescent patients, or cirrhotic patients.⁴¹

Imaging and management of choledocholithiasis can be stratified according to age (increased chance in patients older than 55 years), elevated bilirubin concentration (>1.8 mg/dL), and duct dilation (>6 mm).⁴² However, even if this combination of clinical data suggests a high likelihood of choledocholithiasis, this assessment may be incorrect in more than two thirds of patients.⁴³ Thus, imaging with either MRCP or the more invasive EUS, both being equally the best imaging modalities for choledocholithiasis diagnosis,⁴⁴ is usually obtained before management with ERCP.

With the present use of accurate imaging for choledocholithiasis before ERCP and stone removal, the meticulous ERCP technique, previously needed to identify the stone, is now usually lacking. Ideally, the cannula should be placed with its tip in the most distal portion of the CBD with slow injection of contrast material. The early duct filling is imaged to best

Figure 74-18 Post-liver transplantation patient. There is a very tight anastomotic stricture (arrow) in this liver transplant patient with no upstream dilation. There is also ectasia of the recipient duct without evidence of obstruction. Subsequent balloon dilation and plastic stent placement were used in treatment.

display the offending stone, which has typically migrated to the distal duct. Present practice frequently has a deeper cannula placement and minimal injection of contrast material. These images are used to verify the cannula's position within the CBD so sphincterotomy and stone removal can continue. The decreased amount of intraluminal injection of contrast material is of clinical benefit to decrease the chance of sepsis. Endoscopic management of choledocholithiasis is 90% successful with an approximate 10% complication rate.⁴⁰

In the acute time frame, choledocholithiasis can lead to ascending cholangitis. If ascending cholangitis is suspected, the endoscopist needs to be wary of overinjection of contrast material. Changes of ascending cholangitis can be seen at ERCP: a variable degree of duct dilation with normal-appearing wall; mild irregularity of the wall with “pleating” of diverticula; or marked irregularity of the wall, which may represent necrosis, leading to communicating cavities in the liver from hepatic abscess formation. If the ductal stones go untreated, chronic changes of diffuse stricturing can occur, resulting in secondary sclerosing cholangitis.

Gallstones still residing in the gallbladder can also affect the extrahepatic biliary tree in the Mirizzi syndrome. This is a rare manifestation of gallstone disease, seen in only 0.1% to 0.7% of patients with gallstones.⁴⁵ This syndrome is thought to develop from recurrent bouts of cholecystitis, which contracts the gallbladder around and pushes a stone into Hartmann's pouch or the cystic duct. This pressure, combined with the relatively parallel orientation of the cystic duct with the CHD, can initially

Figure 74-19 Chronic pancreatitis causing distal common duct stricturing. **A.** The hourglass appearance is typical for distal ductal stricture in the chronic pancreatitis patient. **B.** In another patient, there is a rapidly progressive, focal narrowing that could suggest pancreatic carcinoma. However, this aggressive-looking stricture is related to chronic pancreatitis.

cause a lateral to medial indentation on the CHD. With continuing pressure, the stone can be driven progressively into the CHD or CBD lumen. When it is completely intraluminal, this stone can cause obstruction, frequently at the junction of the suprapancreatic and intrapancreatic portion of the common duct. Various classifications have been used to describe this syndrome.⁴⁵ This syndrome has also been associated with an increased chance of cholangiocarcinoma.^{45,46}

MRI and MRCP are the imaging modalities of choice to make the diagnosis of Mirizzi syndrome. ERCP can also be used both for diagnosis and for possible decompression of the bile duct obstruction before surgery (Fig. 74-20).

Autoimmune processes can also lead to biliary stricture disease. Primary sclerosing cholangitis is thought to have at least some component of autoimmune disease. More recently, immunoglobulin G4-related sclerosing disease (formally called autoimmune pancreatitis) has become more widely appreciated as a cause of pancreaticobiliary disease as well as of other disease processes associated with this entity.

In primary sclerosing cholangitis, an inflammatory or fibrotic process diffusely affects the biliary tree, with rare sparing of the extrahepatic duct (Fig. 74-21). Early on, there will be a lack of distensibility of the most peripheral intrahepatic duct system, causing a pruned appearance at ERCP. In the gentle flowing appearance, the intrahepatic ducts lose their normal acute angles and become stiff. As the disease progresses, short focal strictures develop with the defining characteristic of a relative lack of significant upstream dilation. With further progression, there is some interval dilation between the series of focal strictures, leading to a beaded appearance. Diverticula as well as small intraductal stones can develop.

The strictures inexorably progress to cause worsening obstruction. Major central strictures can be targeted for endoscopic dilation to provide some relief. The stricture disease progresses, at a variable rate, leading to end-stage liver disease. Death occurs without liver transplantation. Cholangiocarcinoma is

another potentially lethal complication, being seen in 5% to 20% of patients with primary sclerosing cholangitis.^{47,48}

Although MRCP has replaced ERCP in the initial work-up for suspected primary sclerosing cholangitis, a false-negative MRCP study can be obtained in the early time course of this disease.⁴⁸ The greater spatial resolution at ERCP and the increased pressure from active injection at ERCP will enable the subtle pruning of early primary sclerosing cholangitis to be visualized. Central dominant stricture dilation and brushings of suspicious strictures can also be obtained during ERCP.

Immunoglobulin G4-related sclerosing disease has become much better recognized as a cause of biliary tract strictures. Lymphoplasmacytic cells can infiltrate the biliary tree to create various morphologic appearances of the stricture: a single intrapancreatic CBD stricture simulating pancreatic cancer; multiple strictures in both the intrahepatic and extrahepatic biliary tree that could suggest primary sclerosing cholangitis; multiple intrahepatic strictures only; a hilar stricture to suggest a Klatskin tumor; and a combination of both a hilar and a distal CBD stricture.^{49,50}

The cholangiographic appearance of the biliary tract findings by itself will not allow the diagnosis of immunoglobulin G4-related sclerosing disease to be made. Information obtained from histology, imaging, serology, other organ involvement, and response to steroid therapy (HISORT criteria) in various combinations is required for the diagnosis.^{49,51} ERCP can display the bile duct abnormalities as well as the pancreatic duct findings of this disease (Fig. 74-22). MDCT and MRI are also helpful in displaying not only potential duct abnormalities but also any other abdominal organs that may be involved in this disease complex: pancreatic parenchyma, renal parenchyma, and retroperitoneal fibrosis.

Acquired immunodeficiency syndrome (AIDS) is another immunologic disease that affects the biliary tract, causing AIDS cholangiopathy. Even as the successful treatment of AIDS decreases the incidence of this cholangiopathy, it can still be seen in the severely immunocompromised AIDS patient

Figure 74-20 Mirizzi syndrome. **A.** A 54-year-old woman with 10 years of intermittent right upper quadrant pain now presents with increasing right upper quadrant pain and elevated liver function test results. The initial ERCP shows proximal common hepatic duct obstruction (arrowhead) with adjacent curvilinear calcifications (arrows). Also note the distal common duct stone (asterisk). **B.** After drainage with a plastic stent for 1 month, ERCP demonstrates a contracted gallbladder (arrows) with a moderate-sized stone at the gallbladder neck (arrowhead). The common hepatic duct is now patent but still narrowed by the adjacent inflammatory process.

Figure 74-21 Primary sclerosing cholangitis appearances.

A. ERCP demonstrates mild stiffness of the extrahepatic biliary tree with minimal narrowing. There is moderate, diffuse stricturing of the intrahepatic duct system. The stricture seen in the left hepatic duct (arrow) is caused by cholangiocarcinoma. **B.** A second patient demonstrates the somewhat unusual occurrence of diffuse intrahepatic biliary tract disease with no involvement of the extrahepatic biliary tract. **C.** The third patient demonstrates advanced, severe, diffuse disease resulting in irregular, shaggy mucosa with diverticular formation.

Figure 74-22 Immunoglobulin G4–related sclerosing disease. **A.** There is severe intrahepatic biliary tract stricturing of the right intrahepatic duct system with mild irregularity of the extrahepatic biliary tract that simulates primary sclerosing cholangitis. **B.** The distal extrahepatic biliary tract is strictured along with the diffusely irregular and narrowed pancreatic duct. **C.** After steroid therapy, there has been a marked improvement of the biliary tract. **D.** The pancreatic duct is now nearly normal after steroid treatment.

(CD4 count $<100/\text{mm}^3$) and in the patient population with better preserved immunologic function but not responding to first-line therapies for human immunodeficiency virus infection.⁵² Imaging is still a critical part in the diagnosis of AIDS cholangiopathy; however, clinical information and biochemical data are also important in establishing this diagnosis.

AIDS cholangiopathy can be manifested by a variety of stricture types occurring alone or in combination: a short, papillary stenosis type of narrowing; a longer, 1- to 2-cm extrahepatic biliary tree stricture; or an intrahepatic biliary component that simulates primary sclerosing cholangitis findings (Fig. 74-23).

MRCP is again the imaging examination of choice to display the stricture disease of the biliary tract. ERCP with endoscopic sphincterotomy can relieve the papillary stenosis type of stricture; endoscopic balloon dilation, possibly with stent placement, can be used for the longer extrahepatic biliary tree stricture. Endoscopic brushings can also be obtained to sample areas suspicious for malignant transformation.

The papillitis present in AIDS cholangiopathy can be similar to another distal duct disorder, sphincter of Oddi dysfunction, a nebulous disorder thought to have a mechanical narrowing or an abnormally contracting sphincter of Oddi. Various combinations of “biliary pain,” elevated liver function test results,

increased bile duct diameter, and abnormal sphincter of Oddi manometry are used to place a patient into a type I through type III classification,^{53,54} although this classification has undergone further examination, with some suggesting the need for revision.^{55,56}

Noninvasive tests using nuclear medicine and MRI have been tried to diagnose sphincter of Oddi dysfunction, with mixed results.⁵⁵ ERCP, including sphincter of Oddi manometry when necessary, gives the best results for this diagnosis while also allowing treatment with biliary or, rarely, pancreatic endoscopic sphincterotomy.⁵⁵

ERCP can demonstrate a short, tight stricture at the sphincteric segment (Fig. 74-24) or may be unremarkable. An upstream, dilated CBD may be present. Previously, 12 mm or more was used for abnormal ductal dilation, but now some experts have decreased this diameter to 8 mm or more.⁵⁴ Delayed drainage of either duct system can also be important. The biliary tract, after cholecystectomy, should be completely drained of injected contrast material by 45 minutes. The pancreatic duct should be emptied by 10 minutes after injection. Another important aspect of ERCP is to rule out other diagnoses that may simulate sphincter of Oddi dysfunction. Stones, sludge, and periampullary tumors can all cause sphincter of Oddi dysfunction symptoms and findings.

With increased immigration from Southeast Asia, the inflammatory process of recurrent pyogenic cholangitis, previously referred to as Oriental cholangitis, is more frequently seen in the United States. The presumed combination of infection and obstruction causes the development of intrahepatic and extrahepatic calcium bilirubinate pigment stones.

Figure 74-23 AIDS cholangiopathy. ERCP demonstrates a long stricture of the distal common bile duct (arrow) continuing into the sphincteric segment. The biliary tract above this is mildly dilated with diffuse irregularity of both the intrahepatic and extrahepatic biliary tree. Subsequent endoscopic balloon dilation was used to treat this stricture.

These “stones” tend to be relatively soft, being of mud or paste consistency.

Although CT or MRI may be the first imaging test that can help in the diagnosis and serve as a roadmap for stone location, ERCP can successfully remove the extrahepatic biliary tree stones. The intrahepatic ducts will usually demonstrate angled branching, with stenotic segments making the location of these stones difficult to remove from below. At cholangiography, the left and right posterior duct systems tend to be more heavily involved. Not only does the infection’s fibrotic process cause more central duct strictures, but the peripheral ducts rapidly taper, resulting in the so-called arrowhead sign (Fig. 74-25). The

Figure 74-25 Recurrent pyogenic cholangitis. ERCP demonstrates many cholangiographic findings of this disease: diffuse ductal dilation that results from an inflammatory papillitis; a moderate-sized intrahepatic stone (arrowhead); and rapidly tapering peripheral intrahepatic ducts, creating the arrowhead appearance.

Figure 74-24 Sphincter of Oddi dysfunction. **A.** ERCP shows tight, focal narrowing of the distal common bile duct (arrow). There is upstream dilation. **B.** An image 45 minutes after examination termination reveals contrast material remaining in both the biliary tree and pancreatic duct to confirm obstruction of both systems.

arrowhead appearance is made even more prominent by the tendency of the biliary tract to be diffusely dilated, presumably because of an inflammatory papillitis.

Some other infectious and inflammatory agents can cause biliary narrowing at the hilum from enlarged lymph nodes, such as sarcoid or tuberculosis. Another rare hilar inflammatory process of unknown etiology is the inflammatory pseudotumor or the malignant masquerade. This infiltrating, cicatrizing process tends to occur at the hilum and may extend to the first or second order of the intrahepatic biliary tree. Its appearance is impossible to differentiate from hilar cholangiocarcinoma (Fig. 74-26).

Figure 74-26 Inflammatory pseudotumor. The 78-year-old man presented with jaundice. At cholangiography, there is a tight stricture of the most proximal common hepatic duct (arrow) with upstream dilation. At surgery, a focal inflammatory process was seen in this area, and only inflammatory tissue was found at histology.

Various prior therapeutic treatments can cause biliary strictures. External beam radiation therapy can stricture the bile duct segment within the radiation field (Fig. 74-27A). Strictures can also be seen with the use of intra-arterial chemotherapy (Fig. 74-27B). The bile duct segment near the site of percutaneous ablation can also be narrowed.

There are a number of other inflammatory causes of biliary stricture formation. Cirrhosis can affect the intrahepatic biliary tree with a corkscrew appearance. Cystic fibrosis can have both intrahepatic and extrahepatic biliary tree involvement. Primary biliary cirrhosis will cause diffuse intrahepatic duct strictures as a manifestation of developing cirrhosis. Blunt trauma, with its shearing forces, can produce stricturing at either the hilum or the junction of the suprahepatic and intrahepatic biliary tract. Eosinophilic cholangiopathy is a rare cause of biliary tract stricturing.⁵⁷ Portal biliopathy is a rare condition that occurs with portal hypertension as the recruited bile duct wall vessels enlarge and narrow the extrahepatic duct but do not cause obstruction.⁵⁸ Secondary sclerosing cholangitis can be meant for many of the diseases described so far, but some use this term for the stricturing specifically related to chronic choledocholithiasis. Even periampullary duodenal diverticula may cause extrinsic narrowing of the adjacent biliary tract segment.

Pancreas Neoplasia

Primary pancreatic ductal adenocarcinoma represents more than 90% of pancreatic tumors. Previously, ERCP was an important imaging tool in its diagnosis, having a sensitivity and specificity of 92% and 96%, respectively.⁵⁹ During the past decade, ERCP has steadily been replaced by MDCT, MRI and MRCP, and EUS for diagnosis.^{60,61} MPD injection for diagnostic purposes is no longer used. As discussed earlier, ERCP is now used only in a therapeutic role if treatment for obstructive jaundice is needed, when tissue may also be obtained.

ERCP previously also had a role in the interrogation of the intraductal papillary mucinous neoplasm. ERCP would be used to show ectasia of the MPD or its side branches, to establish the communication of cysts with the MPD, to demonstrate the rare

Figure 74-27 Post-therapy biliary tract changes. **A.** ERCP in this patient having undergone radiation therapy for gastric carcinoma demonstrates diffuse extrahepatic biliary tree narrowing, worse distally. **B.** This patient has central duct narrowing after undergoing intra-arterial hepatic chemotherapy for colon cancer.

ductal filling defect, or to obtain brushings or pancreatic fluid samples. However, MDCT, MRI, and MRCP as well as EUS, when it is needed, have replaced ERCP to the extent that it is no longer recommended for imaging of intraductal papillary mucinous neoplasm.⁶²

Numerous other tumors affect the pancreas: serous microcystic adenoma, mucinous cystic neoplasm, neuroendocrine tumor, solid and pseudopapillary endothelial neoplasm, lymphoma, and metastatic disease. ERCP has again been replaced by MDCT, MRI and MRCP, and EUS. In general, all of these tumors tend to displace the MPD. They may cause a variable amount of upstream obstruction from extrinsic pressure, but they do not tend to invade the MPD.

Pancreas Inflammation

Inflammation of the pancreas can be divided into acute and chronic pancreatitis. Idiopathic pancreatitis is used when the etiology of recurrent bouts of acute pancreatitis is not found on the initial work-up. As has been true in many aspects of the pancreaticobiliary tract, the use of ERCP for diagnosis has given way to noninvasive imaging procedures. ERCP is again left mainly for its therapeutic potential.

Although acute pancreatitis has numerous possible causes, alcohol use and gallstones make up the majority of causes. As previously noted, MRCP or EUS now is the first choice in imaging for the diagnosis of choledocholithiasis. In the management of acute pancreatitis, there is still debate as to the necessity of obtaining ERCP with stone removal in biliary pancreatitis. ERCP with endoscopic sphincterotomy and stone removal is not thought to be of help in mild pancreatitis, in which the offending stone presumably is relatively small and passes spontaneously from the biliary tree.^{63,64} However, some would suggest that with a component of biliary tract obstruction or cholangitis, ERCP with stone removal is warranted.⁶³ For any use of ERCP in acute pancreatitis, injection into the MPD is to be avoided.

Previously, ERCP played a prominent role in the diagnosis of chronic pancreatitis (Fig. 74-28) by assessing side branch and main duct changes according to the Cambridge classification.⁶⁵ EUS and MRCP, with the possible addition of secretin with MRCP, are the relatively noninvasive first choices in

Figure 74-28 Mild chronic pancreatitis. The main pancreatic duct is stiff, and there are scattered abnormal side branches (arrow).

imaging of chronic pancreatitis.^{63,66} ERCP, with its endoscopic interventional procedures, can be used to help decompress the MPD and to decrease the pain associated with chronic pancreatitis: endoscopic pancreatic sphincterotomy; balloon dilation of MPD strictures; long-term pancreatic stent placement; and ductal stone or concretion removal (usually made more successful with prior stone extracorporeal shock wave lithotripsy).⁶⁷⁻⁷⁰

Idiopathic pancreatitis is used to describe the 10% to 30% of recurrent acute pancreatitis in which no etiology is found on initial work-up. ERCP can be helpful here as well. Pancreatic sphincter of Oddi manometry can establish the diagnosis of pancreatic sphincter of Oddi dysfunction with subsequent treatment with endoscopic sphincterotomy. ERCP can also be used to aspirate bile to make the diagnosis of microlithiasis, which should lead to cholecystectomy.

Interventional ERCP is also used in the management of pancreatic duct leaks. Most of these leaks are related to severe acute or chronic pancreatitis (Fig. 74-29), but there are other causes as well, such as prior surgery, trauma, or tumor.^{67,71,72} Most success is obtained by extending a pancreatic duct stent across the affected duct segment.⁷³ This pancreatic duct stenting, however, does not provide effective treatment for complete duct disruption, which can lead to the disconnected duct syndrome. In this situation, the leaking pancreatic enzymatic digestive secretions contaminate the pancreatic bed and possibly beyond.⁶⁷ More aggressive measures will be needed with complete disruption.

Endoscopic intervention can also be used in the effective treatment of peripancreatic pseudocysts. Previously, pseudocyst size, reaching 6 cm, was thought to be a major indication for treatment.⁷⁴ Some now suggest that treatment should be reserved for persistent pain, local gastrointestinal tract or biliary tract obstruction, increasing abdominal or pleural fluid, increasing cyst diameter, or signs of pseudocyst complication (such as hemorrhage or infection).⁷⁵

The use of transmural endoscopic treatment requires the pseudocyst to be closely applied with the stomach or duodenum, usually considered to be within 1 cm.⁷⁶ Endoscopy alone or with EUS is used to facilitate the puncture from the gastrointestinal tract segment into the cyst. At least two stents are subsequently placed for adequate drainage. If necrotic debris is present, more stents can be placed or a nasocystic tube can be added.⁷⁵ If needed, subsequent removal of nondrained necrotic material can be obtained by aggressive balloon dilation at the original puncture site with advancement of the endoscope into the cavity for debris removal.⁷⁵

Transpapillary drainage of pseudocysts can also be obtained if the cyst is less than 6 cm and communicates with the MPD.^{75,77,78} A large-bore stent is placed across the segment of duct disruption or into the cyst itself.

Complications of Endoscopic Retrograde Cholangiopancreatography

The major complications occurring with ERCP are pancreatitis, hemorrhage, perforation, and biliary tract infection. Pancreatitis is the most common, ranging from approximately 2% to 16% but most commonly reported in 3.5% of cases.⁷⁹⁻⁸²

Figure 74-29 Chronic pancreatitis and endoscopic intervention. **A.** On initial ERCP, there is a subtle extravasation into two pseudocysts (arrows) and a stricture in the mid main pancreatic duct (arrowhead). **B.** Subsequently, a wire is placed into the pancreatic duct across the two segments communicating with the pseudocysts (arrows) and stricture (arrowhead). **C.** A final image from this first examination demonstrates the plastic stent crossing the area of the two pseudocysts (arrows) and projecting across the presumed area of main pancreatic duct stricture. **D.** ERCP 5 months after the initial examination demonstrates that there is no filling of either pseudocyst, and the mid main pancreatic duct stricture (arrowhead) has improved.

Hemorrhage after ERCP occurs in about 1.3% of cases, with the majority of bleeding episodes being minor.⁸² This complication is much more likely to be related to sphincterotomy than when only a diagnostic examination is obtained. The bleeding usually exits into the gastrointestinal tract and much less commonly into the ductal system.⁷⁹

Perforation is seen in 0.1% to 0.6% of examinations.⁷⁹ It can be related to guidewire manipulation or perforation at

the ampulla of Vater during endoscopic sphincterotomy or at a site separate from the papilla in the gastrointestinal tract.⁸³

Infection is related to the biliary tract or even the gallbladder. Cholangitis is present in less than 1% of cases and appears to be related to extent of ductal manipulation, patient factors, and operator experience.^{79,84-86} Cholangitis is reported in 0.2% to 0.5% of examinations.^{84,85}

Magnetic Resonance Cholangiopancreatography

ANN S. FULCHER | MARY ANN TURNER

CHAPTER OUTLINE

Technique

Clinical Applications

Bile Duct Calculi

Neoplasms

Congenital Anomalies

Postoperative Alterations of the Pancreaticobiliary Tract and Gastrointestinal Tract

Primary Sclerosing Cholangitis

Pancreatitis

Acute Pancreatitis

Chronic Pancreatitis

Gallbladder Diseases

Since the first clinical application of magnetic resonance cholangiopancreatography (MRCP) in the early 1990s, MRCP has evolved from a technique with questionable potential for imaging of the biliary tract and pancreatic duct to one that is now recognized as a pivotal tool for diagnosis of pancreaticobiliary disease. In fact, the evolution of MRCP has been such that at many centers, MRCP has replaced diagnostic endoscopic retrograde cholangiopancreatography (ERCP) in a number of clinical scenarios. A prospective survey revealed that MRCP findings enhance the diagnostic confidence of gastroenterologists and decrease the need for invasive procedures.¹

For many years, ERCP has been considered the standard of reference for imaging of the biliary tract and pancreatic duct because of its ability to render high-quality images of the ducts. However, ERCP is an invasive examination associated with complications that occur in up to 5% of all attempts and that range from subclinical to life-threatening.² Those complications include pancreatitis, hemorrhage, cholangitis, and gastrointestinal tract perforation.

The relatively rapid acceptance of MRCP is related, in large part, to its ability to provide images of the ducts similar to those of ERCP. These images can be obtained without the associated complications of ERCP while offering comparable sensitivity, specificity, and accuracy. In addition, MRCP is readily performed in the outpatient setting and does not expose patients to ionizing radiation. In most instances, performance of MRCP does not require administration of sedation. In contrast to ERCP, MRCP readily depicts ducts proximal to a high-grade obstruction as well as ducts in patients with surgical alterations of the biliary tract and gastrointestinal tract, such as biliary-enteric anastomoses. Although ERCP yields exquisite images of the ductal systems, it provides no direct information about the

solid organs and vessels of the abdomen. However, when MRCP is performed in conjunction with conventional magnetic resonance imaging (MRI) and, when necessary, magnetic resonance angiography (MRA), a comprehensive examination is achieved. This information assists in determining resectability of neoplasms, such as pancreatic carcinoma, and in detecting complications of primary sclerosing cholangitis, such as cirrhosis and cholangiocarcinoma.

Technique

Before acquisition of the MRCP image, many advocate the use of heavily T2-weighted, non-fat-suppressed sequences, such as the half-Fourier acquisition single-shot turbo spin-echo (HASTE) sequence, to provide an overview of the entire abdomen (Fig. 75-1A). These comprehensive images allow visualization of the solid organs as well as of the pancreaticobiliary tract and gallbladder. The MRCP image is then acquired. This can be achieved by use of a two-dimensional (2D), heavily T2-weighted, fat-suppressed, breath-hold sequence. This sequence can provide single thick-slab images with slice thicknesses ranging from 10 to 70 mm and multiple thin-slab images with slice thicknesses ranging from 2 to 5 mm^{3,4} (Fig. 75-1B-D). The images depict the biliary tract, pancreatic duct, and gallbladder as high signal intensity structures. Multiple acquisitions are conducted in the coronal and coronal oblique planes to optimally image the ducts. In addition, the axial plane is useful in distinguishing stones, which layer in the dependent portion of the duct, from pneumobilia, which is nondependent. In general, the thin-slab images allow improved delineation of the finer details of the ductal systems, whereas the thick-slab images provide comprehensive views of the ducts that assist in the depiction of diffuse ductal diseases, such as primary sclerosing cholangitis. Although the thin-slab images may be manipulated with a maximum intensity projection (MIP) algorithm, most diagnostic decisions are made directly from the 2D images. In interpreting MIP images, it should be remembered that at times the high signal intensity that is characteristic of MIPs may obscure subtle intraductal filling defects, such as small stones.

More recently, three-dimensional (3D) sequences used in conjunction with respiratory triggering, thin sections (1-2 mm), and high matrices have been used to generate MRCP images. With this technique, the source images can be viewed as individual images, much like MRCP images acquired with 2D sequences. The advantage of 3D imaging is that it yields isotropic images that can be reformatted in any plane, thereby obviating the need to acquire images in multiple planes.

Some investigators advocate the performance of contrast-enhanced MRCP with 3D T1-weighted sequences and hepatocyte-specific contrast agents that are excreted into the biliary tract. These agents are divided into two major

Figure 75-1 MRCP technique: normal anatomy. **A.** Coronal, non-fat-suppressed HASTE image provides an overview of the abdomen by depicting the liver and spleen as well as the distal half of the bile duct (arrow) and pancreatic duct (arrowhead) in the head of the pancreas. **B.** Coronal, fat-suppressed, thick-slab (40 mm) MRCP shows the intrahepatic bile ducts, extrahepatic bile duct (arrow), pancreatic duct (arrowheads), and gallbladder (g) in a single image. **C.** Coronal oblique, fat-suppressed, thin-slab (5 mm) MRCP demonstrates the finer details of the extrahepatic bile duct (arrow) compared with the thick-slab MRCP. Extrinsic compression (curved arrow) of the proximal extrahepatic bile duct by the crossing hepatic artery is noted. **D.** Coronal oblique, fat-suppressed, thin-slab (5 mm) MRCP reveals the gallbladder (g), the cystic duct (double arrow), and a portion of the extrahepatic bile duct (arrow).

categories: manganese-based agents (no longer available in the United States) and gadolinium-based agents, such as gadobenate dimeglumine and gadoxetate.⁵ MRCP performed with T1-weighted sequences and a manganese-based agent has been shown useful in the detection of biliary complications after laparoscopic cholecystectomy and in depicting the intrahepatic bile ducts in living liver transplant donor candidates.^{6,7}

The 2D and 3D techniques allow excellent depiction of the pancreatic duct in most cases. However, in those instances in which the pancreatic duct is not well visualized or determination of pancreatic exocrine function is desired, secretin-enhanced MRCP may prove useful.⁸

Whereas the majority of MRCP studies are performed on 1.5T MRI scanners, a growing number of MRCP studies are being performed on 3.0T MRI scanners, given their increased availability and use. Although 3T scanners may improve image quality and therefore improve ductal delineation, 3T scanners produce increased susceptibility artifacts compared with 1.5T scanners.⁹

Clinical Applications

BILE DUCT CALCULI

Historically, many patients with suspected choledocholithiasis and a normal sonogram or computed tomography (CT) scan underwent diagnostic ERCP to determine the presence or absence of stones. The introduction of MRCP provided a long-awaited, noninvasive alternative to diagnostic ERCP for the detection and exclusion of common bile duct stones. However, for MRCP to gain widespread acceptance, it had to compare favorably with ERCP. In an analysis of 72 patients studied with intraoperative cholangiography and ERCP, Frey and associates¹⁰ found a sensitivity of 90% and a specificity of 98% for ERCP in the setting of suspected choledocholithiasis.

Initial reports of MRCP in the detection of common bile duct stones noted sensitivities as low as 81%.¹¹ However, technical advances in MR hardware and the introduction of sequences that allowed breath-hold imaging and that suppressed artifacts

arising from surgical clips and bowel gas improved MRCP image quality substantially, which in turn enhanced the MRCP diagnosis of common bile duct stones. Subsequent studies performed with state-of-the-art scanners and sequences demonstrated sensitivities of 90% to 100%, specificities of 92% to 100%, and positive predictive value of 96% to 100%, matching and in most cases exceeding those of ERCP.^{3,12-16} Although many physicians focus on the sensitivity offered by a technique, it is equally important to consider the negative predictive value. The negative predictive values of MRCP are high, ranging from 96% to 100%.^{3,14,17} Therefore, if an MRCP study is interpreted as negative for common duct stones, one can be confident that stones are not present in most cases and ERCP can be avoided.^{3,17} In fact, one of the major benefits of MRCP in the setting of suspected biliary calculi is the reduction of unnecessary ERCP studies.¹⁶

In the setting of symptomatic gallstones, MRCP has been shown to be highly accurate in the detection of coexistent choledocholithiasis in patients with high, moderate, and low risks for harboring common bile duct stones based on clinical, laboratory, and sonographic findings.¹² Kim and colleagues¹²

recommended that MRCP be performed before cholecystectomy in patients with a moderate or high risk of common bile duct stones in an effort to reduce morbidity associated with undetected choledocholithiasis and to decrease the performance of purely diagnostic ERCP.

In addition to the detection of common bile duct stones, MRCP performs well in the detection of intrahepatic stones. One study revealed that the sensitivity and specificity of MRCP for detection of intrahepatic stones were 97% and 93%, respectively, whereas those of ERCP were 59% and 97%, respectively.¹⁸

Both extrahepatic and intrahepatic bile duct stones are seen as well-defined, low signal intensity filling defects in the high signal intensity bile (Fig. 75-2). MRCP has been shown to detect stones as small as 2 mm even in normal-caliber ducts.³ Although the coronal and coronal oblique planes demonstrate stones in most instances, at times it is helpful to acquire MRCP images in the axial plane to detect small stones and to differentiate stones that lie in the dependent portion of the duct from pneumobilia that lies in the nondependent portion of the duct (Fig. 75-3).

Figure 75-2 Multiple extrahepatic and intrahepatic bile duct calculi. **A.** Coronal HASTE MRCP provides a comprehensive image of the abdomen by showing multiple, low signal intensity calculi in the dilated extrahepatic bile duct (arrows), central intrahepatic ducts (arrowheads), and gallbladder (g). **B.** Thin-slab MRCP focusing on the distal bile duct (arrows) shows multiple intraductal calculi as well as gallbladder calculi (arrowheads). The fluid-filled duodenum (d) is noted. **C.** Thin-slab MRCP shows stones in the proximal extrahepatic bile duct (arrow), central intrahepatic ducts (arrowheads), and gallbladder (g).

Figure 75-3 Small bile duct calculi: value of axial MRCP. **A.** Thin-slab MRCP reveals small, low signal intensity foci in the distal bile duct (arrow) later removed during therapeutic ERCP. **B.** Axial MRCP shows the small, low signal intensity stones layering in the dependent portion of the intrapancreatic bile duct (arrow), with high signal intensity bile seen anteriorly in the duct. A similar stone-bile level (arrowheads) is noted in the gallbladder.

Although MRCP performs well in the detection of stones, one must be aware of mimickers of stones that may result in false-positive diagnoses. These include pneumobilia, en face visualization of the cystic duct inserting into the bile duct, and compression of the duct by an adjacent vessel.^{19,20}

NEOPLASMS

MRCP is useful in the evaluation of suspected malignant neoplasms of the pancreaticobiliary tract. Multiple studies have demonstrated the ability of MRCP to determine the presence, level, and type of malignant disease with a high degree of accuracy.^{3,21-25} In a study of 62 patients with biliary obstruction, Kim and associates²⁶ demonstrated that the addition of conventional MRI to MRCP significantly improves the accuracy in the diagnosis of pancreaticobiliary disease and aids in the differentiation of benign from malignant causes of biliary dilation. When MRCP is supplemented by conventional MRI and MRA, a comprehensive examination results that allows depiction of the pancreaticobiliary tract, solid organs, and vasculature, which in turn permits determination of resectability of neoplastic disease. This comprehensive examination is most beneficial for patient care. Specifically, if a neoplasm is deemed resectable, the patient should be spared an unnecessary ERCP examination and stent placement as there is no established role for preoperative biliary drainage by ERCP in these patients.²⁷ On the other hand, if a neoplasm is deemed unresectable, the patient may be spared an unnecessary laparotomy. An additional advantage of MRCP offered in the setting of pancreaticobiliary tract malignant neoplasms is that MRCP depicts the entire biliary and pancreatic duct even in the presence of high-grade strictures and allows planning of surgical and percutaneous interventions.

Pancreatic Carcinoma

With the use of newer scanners and sequences that afford high-resolution imaging, MRCP not only readily identifies the ductal dilation that occurs as the result of pancreatic carcinoma but also depicts the malignant ductal strictures themselves and localizes the neoplastic process to the pancreas. MRCP depicts

bile duct involvement by pancreatic carcinoma as an abrupt transition between the dilated suprapancreatic duct and the markedly narrowed intrapancreatic duct, often referred to as a rat-tail configuration (Fig. 75-4A, B). In the case of pancreatic head carcinoma obstructing the bile and pancreatic ducts, MRCP shows dilation of both ducts, known as the double duct sign. Whereas the double duct sign is often seen in association with pancreatic head carcinoma, it is a nonspecific sign that may be due to a benign or malignant process involving the pancreatic head.²⁸ In the setting of carcinoma involving the body or tail of the pancreas, the ductal dilation is limited to the pancreatic duct proximal to the obstruction. Because the entire pancreatic duct is rarely depicted on a single 2D MRCP image, axial MRCP images are often useful in demonstrating the obstructing tumor and the transition between the dilated and nondilated pancreatic duct.

The performance of conventional MRI and MRA in conjunction with MRCP allows determination of resectability (Fig. 75-4C, D). T1-weighted, fat-suppressed, unenhanced sequences are particularly helpful in depicting even small tumors in the pancreas. Pancreatic adenocarcinomas are manifested as areas of low signal intensity against the high signal intensity of the normal pancreatic parenchyma. In addition to detection of the primary tumor, conventional MRI is useful in detecting liver metastases, nodal enlargement, and peritoneal carcinomatosis. MRA plays an important role in detecting neoplastic involvement of the celiac axis, hepatic artery, superior mesenteric artery and vein, and portal vein. In patients with unresectable pancreatic carcinoma, MRCP yields information important in planning of palliative and endoscopic drainage procedures.

In a prospective study of 124 patients with clinical and sonographic findings strongly suggestive of pancreatic neoplasia, Adamek and associates²³ showed that the sensitivity and specificity of MRCP in diagnosis of pancreatic carcinoma (84% and 97%) exceeded those of ERCP (70% and 94%). Unfortunately, the distinction between pancreatic carcinoma and focal chronic pancreatitis will likely remain a problem in some instances despite technical improvements in MRI, MRA, and MRCP.²⁹

Figure 75-4 Unresectable pancreatic head carcinoma: MRCP, MRI, and MRA. **A.** Thick-slab MRCP provides a comprehensive image of the pancreaticobiliary tract that demonstrates high-grade obstruction of the extrahepatic bile duct (arrow) and minor dilation of the pancreatic duct (arrowheads) in the body and tail of the pancreas. **B.** Thin-slab MRCP reveals the finer details of the ductal systems and shows that the extrahepatic bile duct (arrow) is obstructed at the pancreatic head. The intrapancreatic portion of the bile duct (curved arrow) and the pancreatic duct (arrowhead) in the head of the pancreas are narrowed. The distended gallbladder (g) and cystic duct (cd) are shown. **C.** Transverse, T1-weighted, enhanced abdominal MRI shows that the cause of the obstruction is a low signal intensity pancreatic head carcinoma (arrow) that has occluded the distal superior mesenteric vein (arrowhead). There is no evidence of tumor surrounding the superior mesenteric artery (sma). **D.** Coronal, 2D time-of-flight MRI angiogram shows that the pancreatic head mass has occluded the distal superior mesenteric vein (arrowhead) and is inseparable from the common hepatic artery (cha), proximal proper hepatic artery (pha), and gastroduodenal artery (gda). (From Fulcher AS, Turner MA: MR cholangiopancreatography. *Radiol Clin North Am* 40:1367, 2002.)

Cholangiocarcinoma: Hilar and Distal Duct

Hilar cholangiocarcinoma is the most common manifestation of cholangiocarcinoma and is depicted as a high-grade stricture of the confluence of the right and left hepatic ducts. In the past, much emphasis was placed on palliative procedures, such as percutaneous biliary drainage and endoscopic stent placement, because of the poor prognosis associated with this neoplasm. However, with the advent of improved surgical and radiation therapy techniques, greater attention is directed toward imaging examinations that assist in determining disease extent and resectability.

During the past decade, MRCP has become an important tool in the evaluation of cholangiocarcinoma in general and hilar cholangiocarcinoma in particular. Like direct cholangiography, MRCP demonstrates the marked narrowing of the proximal extrahepatic bile duct, the often-present extension to the central right and left hepatic ducts, and the dilation proximal to the obstruction^{30,31} (Fig. 75-5A, B). Because MRCP readily depicts ducts proximal to high-grade obstructions that are

often not opacified at ERCP, MRCP typically is superior in determining disease extent and resectability.^{30,31} As with other pancreaticobiliary tract neoplasms, MRI performed in association with MRCP offers the added advantage of demonstrating disease that has extended from the ducts into the liver and adjacent structures (Fig. 75-5C). These factors have allowed MRCP to assume an important role in the noninvasive evaluation of hilar cholangiocarcinoma and to facilitate planning of surgical, percutaneous, and radiation therapy procedures. Park and coworkers³² demonstrated that MRCP combined with MRI provides information about cholangiocarcinoma extent and resectability comparable to that of multidetector CT with direct cholangiography.

Cholangiocarcinomas that involve the extrahepatic duct distal to the confluence are often referred to as the distal duct type. Distal duct cholangiocarcinomas are seen as strictures or intraductal polypoid masses resulting in biliary obstruction on both MRCP and ERCP. In a retrospective study of 50 patients with extrahepatic bile duct cholangiocarcinoma and 23 patients with benign strictures, MRCP was shown to have

Figure 75-5 Hilar cholangiocarcinoma. **A.** Coronal thick-slab MRCP reveals high-grade isolated obstructions of the central right and left hepatic ducts (arrowheads) due to hilar cholangiocarcinoma. The extrahepatic bile duct distal to the obstruction (arrows) is seen adjacent to the fluid-filled duodenal bulb. **B.** Thin-slab MRCP reveals in greater detail the points of obstruction of the central right and left hepatic ducts (arrowheads) due to cephalad extension of the hilar cholangiocarcinoma. The normal-caliber extrahepatic bile duct (arrow) located just distal to the tumor is noted. **C.** T1-weighted, fat-suppressed, unenhanced abdominal MRI reveals low signal intensity tumor (arrows) that has extended beyond the confines of the biliary tract to invade the hepatic parenchyma.

an accuracy comparable to that of ERCP in making the distinction between cholangiocarcinoma and benign strictures.³² Distal duct cholangiocarcinoma confined to the intrapancreatic bile duct is difficult to distinguish from pancreatic head carcinoma with either MRCP or ERCP (Fig. 75-6). However, the clinical impact of this deficiency is of no consequence as the treatment of both tumors is identical and is predicated on resectability.

Intraductal Papillary Mucinous Neoplasm of the Pancreas

Intraductal papillary mucinous neoplasms (IPMNs) are categorized as main duct type and branch duct type, depending on the duct of origin, and may be benign or malignant. IPMNs are well demonstrated on MRCP because they produce mucin, which appears as high signal intensity within the ducts.³³⁻³⁵ MRCP can reveal the entire spectrum of IPMNs—main duct dilation, cystic dilation of the side branches, nodules, septa, and intraductal filling defects—and is able to show communication between the tumor and the pancreatic duct (Fig. 75-7). A study of 34 IPMNs in 31 patients examined with MRCP and correlated with surgical and pathologic findings revealed that intraductal filling defects are indicative of malignant disease and that diffuse dilation of the main pancreatic duct of more than 15 mm in main duct-type tumors is strongly associated with malignant transformation.³³ In branch duct-type tumors, the absence of main pancreatic duct dilation suggests a benign tumor.

CONGENITAL ANOMALIES

Choledochal or Bile Duct Cysts

MRCP reliably detects choledochal or bile duct cysts in adults and children and provides diagnostic information equivalent to that of ERCP without the risk of complications³⁶⁻³⁹ (Fig. 75-8). MRCP nicely delineates the extent of the cyst and detects anomalous pancreaticobiliary junctions, critical factors in planning of cyst excision and bile duct reconstruction.⁴⁰ Matos³⁶ and Yu⁴¹ and their colleagues noted that the accuracy of MRCP in the detection of anomalous pancreaticobiliary junctions is comparable to that of ERCP. For these reasons, MRCP has been proposed as the imaging modality of choice in evaluation of choledochal cysts.^{37,38}

Anatomic Variants of the Biliary Tract

Anatomic variations of the biliary tract occur in up to 37% of individuals. These include crossover anomalies, such as the dorso-caudal branch of the right hepatic duct entering the central left hepatic duct; trifurcations; accessory or aberrant ducts that enter the extrahepatic duct or cystic duct; and cystic duct variants.⁴² MRCP has been shown to accurately detect these variants.^{43,44} Although ductal variants are usually of no consequence in the general population, they are of great importance in patients undergoing cholecystectomy because some variants predispose to ductal injury.⁴⁵ Ductal variants posed less risk in the era of open cholecystectomy because the biliary tract was

Figure 75-6 Distal duct cholangiocarcinoma. **A.** Coronal thick-slab MRCP shows a high-grade stricture of the intrapancreatic bile duct (arrows) resulting in proximal biliary ductal dilation. The pancreatic duct (arrowheads) is normal in caliber. **B.** T1-weighted, fat-suppressed, unenhanced abdominal MRI shows a mass (arrows) involving the pancreatic head that is low in signal intensity relative to the adjacent normal pancreatic parenchyma (arrowhead). Pathologic analysis revealed cholangiocarcinoma. A large, mesenteric metastasis (m) was present at the time of diagnosis.

Figure 75-7 Malignant intraductal papillary mucinous neoplasm of the pancreas, main duct type. **A.** Coronal thick-slab MRCP reveals a large cystic lesion (arrows) that contains nodular filling defects and that communicates with the main pancreatic duct in the pancreatic body (arrowheads). Incidental note is made of pancreas divisum as evidenced by the horizontal orientation of the main pancreatic duct in the pancreatic head. **B-D.** Coronal oblique thin-slab MRCP, axial HASTE image, and axial T1-weighted, fat-suppressed, contrast-enhanced abdominal MRI show in detail the lobulated cystic mass and the nodular filling defects as well as the dilated pancreatic duct (arrowhead) from which the mass arises.

directly visualized. Because most cholecystectomies are now performed laparoscopically, which does not provide the same degree of direct visualization of the biliary tract, the preoperative recognition of these anomalies is paramount. The increasing use of right lobe living donor liver transplantations has heightened the awareness of radiologists and surgeons alike to the importance of ductal variants such as crossover anomalies (Fig. 75-9). Whereas these variants do not preclude

Figure 75-8 Type 1 choledochal or bile duct cyst. Coronal HASTE MRCP shows fusiform dilation of the majority of the extrahepatic bile duct (arrow) indicative of a type 1 choledochal or bile duct cyst. An anomalous pancreaticobiliary junction (arrowheads) is present. The gallbladder (g) is noted.

Figure 75-9 Aberrant bile duct: crossover anomaly. Coronal thick-slab MRCP depicts the dorsocaudal branch of the right hepatic duct (arrow) entering the central left hepatic duct.

transplantation in most cases, preoperative identification assists in avoidance of inadvertent surgical ligations. Awareness of ductal variants is also important in the planning of complex percutaneous and endoscopic biliary interventions.

Pancreas Divisum

Pancreas divisum occurs in up to 5.5% to 7.5% of the general population.^{46,47} Although most individuals with pancreas divisum demonstrate no symptoms referable to the pancreas, others present with recurrent bouts of unexplained pancreatitis. In fact, pancreas divisum has been shown to occur with significantly greater frequency in patients with acute idiopathic pancreatitis than in the general population.⁴⁶ MRCP has gained an increasingly prominent role in the evaluation of patients with idiopathic pancreatitis because this technique can detect pancreas divisum and other ductal anomalies with a high degree of accuracy. Unlike diagnostic ERCP, MRCP does not carry the risk of inducing pancreatitis in this group of patients who are predisposed to its development.³⁸ Manfredi and associates⁴⁸ noted that secretin-enhanced MRCP assists in identifying pancreas divisum and sometimes the associated cystic dilation of the distal dorsal duct, often referred to as a santorinicele. MRCP is also useful in delineating the ductal changes of chronic pancreatitis: dilation of the main pancreatic duct, side branch ectasia, strictures, and intraductal stones. In addition, T1-weighted, fat-suppressed, unenhanced sequences performed in conjunction with MRCP assist in detecting associated pancreatic atrophy and fibrosis. With these sequences, fibrosis is seen as decreased signal intensity of the pancreas compared with that of the liver secondary to replacement of aqueous protein in the pancreatic parenchyma.

At MRCP, pancreas divisum is usually depicted as two separate drainage systems of the pancreas (Fig. 75-10). The larger dorsal duct drains the majority of the pancreas and enters the duodenum at the minor papilla cephalad to and separate from the ventral duct. The smaller ventral duct drains the inferior pancreatic head and uncinate process and enters the duodenum at the major ampulla with the distal bile duct. For the diagnosis of pancreas divisum to be established at MRCP, care must be taken to ensure that there is no communication between the dorsal and ventral ducts. This is most readily achieved by reviewing the images at a workstation rather than on film.

Postoperative Alterations of the Pancreaticobiliary Tract and Gastrointestinal Tract

Multiple studies have demonstrated the utility and accuracy of MRCP in depicting normal anatomy and pathologic changes of the ducts in patients with postsurgical alterations of the pancreaticobiliary tract and gastrointestinal tract.⁴⁹⁻⁵⁴ Specifically, MRCP readily depicts anastomotic strictures, intraductal stones, bile plugs, and, in some cases, injuries of the ducts after cholecystectomy with sensitivities up to 100%.^{50,52}

MRCP has been used successfully in imaging of patients after cadaveric and living donor liver transplantations, hepatic resection, pancreatoduodenectomy, and creation of a biliary-enteric anastomosis (Fig. 75-11). MRCP is particularly well suited to the evaluation of patients with biliary-enteric anastomoses. The performance of ERCP is difficult if not impossible in these patients because of the surgical alteration of the gastrointestinal

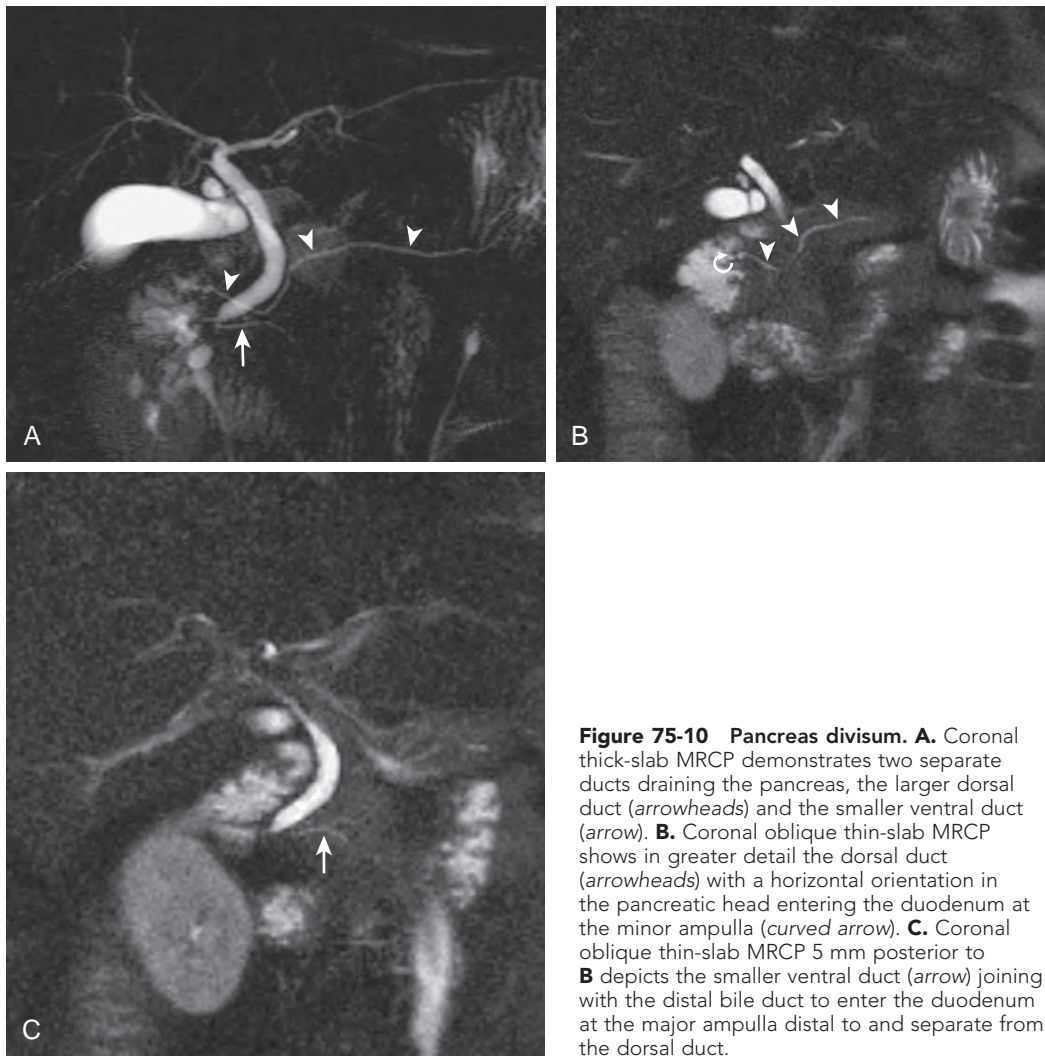

Figure 75-10 Pancreas divisum. **A.** Coronal thick-slab MRCP demonstrates two separate ducts draining the pancreas, the larger dorsal duct (arrowheads) and the smaller ventral duct (arrow). **B.** Coronal oblique thin-slab MRCP shows in greater detail the dorsal duct (arrowheads) with a horizontal orientation in the pancreatic head entering the duodenum at the minor ampulla (curved arrow). **C.** Coronal oblique thin-slab MRCP 5 mm posterior to **B** depicts the smaller ventral duct (arrow) joining with the distal bile duct to enter the duodenum at the major ampulla distal to and separate from the dorsal duct.

Figure 75-11 Biliary-enteric anastomotic stricture and intraductal stones. **A.** Coronal oblique thin-slab MRCP shows dilation of the residual proximal extrahepatic bile duct (arrow) indicative of a stricture of the biliary enteric anastomosis (arrowheads). Intraductal filling defects represent stones that have formed secondary to stasis. The rounded, fluid-filled structure (open arrow) represents the proximal aspect of the jejunal limb. **B.** Direct cholangiography performed during a percutaneous biliary drainage procedure confirms the biliary enteric anastomotic stricture (arrow), intraductal stones (arrowhead), and proximal jejunal limb (open arrow). Slow passage of contrast material occurred from the duct to the jejunal limb.

tract. Before the advent of MRCP, depiction of the ducts in patients with biliary-enteric anastomoses could be achieved only by performing percutaneous transhepatic cholangiography (PTC), which is an invasive procedure associated with complications such as bleeding and infection.

MRCP is often used to evaluate the biliary tract after liver transplantation for complications such as strictures and stones.⁵⁵ ERCP and PTC may lead to serious complications in this group of seriously ill patients. If complications are detected with MRCP, patients can then be referred for therapeutic ERCP or PTC. If complications are excluded with MRCP, the patient will be spared an unnecessary invasive procedure and its attendant complications.

Although MRCP is highly accurate in imaging of the post-operative pancreaticobiliary tract, it is associated with a number of pitfalls and limitations. In patients with biliary-enteric anastomoses, pneumobilia may mimic intraductal stones as both appear as filling defects in the high signal intensity bile. In most instances, the distinction can be made by observing that pneumobilia is located in the nondependent portion of the duct and stones are located in the dependent portion of the duct on coronal and axial images.^{49,50} A limitation of MRCP in the assessment of biliary strictures was noted by Ward and associates,⁴⁹ who found a tendency of MRCP to overestimate the grade of strictures. Finally, despite studies reporting the utility of MRCP performed in conjunction with agents excreted into the biliary tract for detection of bile duct leaks,⁵⁶ it is likely that diagnostic ERCP may remain the primary means of detecting leaks as ERCP also provides access for stent placement in the same setting as the diagnostic ERCP examination. Nevertheless, MRCP has emerged as an accurate, noninvasive means of evaluating the ductal systems in patients with postsurgical alterations of the pancreaticobiliary tract and gastrointestinal tract.

Primary Sclerosing Cholangitis

For many years, direct cholangiography (ERCP and, to a lesser extent, PTC) has been considered the imaging examination of choice for diagnosis of primary sclerosing cholangitis (PSC)

and observation of its progression. Although both ERCP and PTC yield exquisite images of the ducts and provide access for interventions, these invasive examinations place patients at risk of complications such as cholangitis, pancreatitis, hemorrhage, and infection. MRCP provides a noninvasive diagnostic alternative for the evaluation of patients with known or suspected PSC.

Direct cholangiographic findings of PSC include multifocal, annular strictures of the intrahepatic or extrahepatic bile ducts that alternate with normal or slightly dilated segments, resulting in a beaded appearance of the ducts; diverticulum-like outpouchings; mural irregularities; and pruning of the peripheral intrahepatic bile ducts.⁵⁷ Due to technical advances, MRCP is able to depict the fine details of the ducts and to demonstrate the typical ductal abnormalities of PSC with a high degree of accuracy⁵⁸⁻⁶¹ (Figs. 75-12 and 75-13). Vitellas and associates^{60,61} showed that MRCP is superior to ERCP for depiction of intrahepatic ducts and intrahepatic ductal strictures in part because of the ability of MRCP to demonstrate ducts proximal to a high-grade obstruction. MRCP also is useful in detecting recurrent PSC after liver transplantation as MRCP readily depicts the intrahepatic and extrahepatic bile ducts in these patients with a biliary-enteric anastomosis who would otherwise require PTC for the biliary tract to be visualized.⁵⁸ Despite the utility and accuracy of MRCP in the diagnosis of PSC, the distinction between a benign stricture due to PSC and a malignant stricture related to cholangiocarcinoma will likely remain a problem.

A prospective case-control study in which 102 patients (34 with PSC and 68 age-matched controls with hepatobiliary diseases other than PSC) underwent MRCP revealed that MRCP was accurate in detecting and localizing PSC.⁵⁸ In the detection of PSC, for two independent readers, the sensitivities were 85% and 88%; specificities, 92% and 97%; positive predictive value, 85% and 94%; and negative predictive value, 93% and 94%. Interobserver agreement was excellent. All false-positive diagnoses were related to distortion of the ducts by underlying cirrhosis. Five false-negative diagnoses occurred and were related to marked cirrhosis that obscured the intrahepatic ducts in two patients and early changes of PSC that were limited to the peripheral intrahepatic ducts in the remaining three patients.

Figure 75-12 Intrahepatic and extrahepatic primary sclerosing cholangitis. **A.** Coronal oblique thin-slab MRCP depicts strictures (arrows) and dilation of the intrahepatic bile ducts and marked mural irregularity and diverticulum-like outpouchings of the extrahepatic bile duct (arrowheads). **B.** Axial, T1-weighted, fat-suppressed, enhanced image of the abdomen reveals cirrhosis complicating PSC as evidenced by lateral segment (ls) hypertrophy and right lobe (rl) atrophy. Thickening and enhancement of the wall of the proximal extrahepatic bile duct (arrowhead) is noted as well as intrahepatic ductal dilation (arrows).

Figure 75-13 Intrahepatic primary sclerosing cholangitis. Coronal thick-slab MRCP shows dilation (arrowheads) and multiple strictures (arrows) of the intrahepatic bile ducts. The slightly dilated extrahepatic bile duct shows no evidence of PSC.

Talwalkar and colleagues⁵⁹ proposed to determine the average cost per correct diagnosis with MRCP or ERCP as the initial means for the diagnosis of PSC. Seventy-three patients with clinically suspected PSC formed the basis of the study; the prevalence of PSC in the study cohort was 32%. The sensitivity and specificity of MRCP for the diagnosis of PSC were 82% and 98%, respectively. Talwalkar and colleagues⁵⁹ found that the accuracy of MRCP was comparable to that of ERCP and that MRCP resulted in cost savings when it was used as the initial test for diagnosis of PSC in their study population. The value of MRCP in the patient with PSC is enhanced when it is performed in association with conventional MRI, which can demonstrate cirrhosis, portal hypertension, cholangiocarcinoma, and hepatic parenchymal changes related to altered perfusion and inflammation of the bile ducts⁶² (see Fig. 75-12B).

MRCP has emerged as a viable alternative to ERCP in the diagnosis of PSC. The utility of MRCP in this setting is related to its accuracy and noninvasive nature and its ability to depict ducts proximal to a high-grade obstruction. As a result, at some centers, ERCP is now used primarily as a means of gaining access for interventions such as stent placements instead of as a diagnostic tool. Nevertheless, ERCP, and at times PTC, may prove useful in detecting PSC in problematic cases, such as in patients with minor changes of PSC limited to the peripheral intrahepatic ducts.

Pancreatitis

ACUTE PANCREATITIS

The primary role of MRCP in the setting of acute pancreatitis is the identification of structural abnormalities that predispose to its development, such as common bile duct stones, pancreas divisum, and tumors obstructing the pancreatic duct. Depending on the severity of acute pancreatitis, edema of the pancreatic parenchyma may result in smooth narrowing of the

Figure 75-14 Acute pancreatitis. Coronal HASTE reveals dilation of the intrahepatic and suprapancreatic bile ducts and smooth narrowing of the intrapancreatic bile duct (arrows) due to compression by the edematous pancreas. MRCP performed after resolution of acute pancreatitis showed that the duct returned to a normal caliber (not shown).

intrapancreatic bile duct or pancreatic duct (Fig. 75-14). When these findings are confined to the pancreatic head, the ductal narrowing and the pancreatic parenchymal enlargement may mimic pancreatic neoplasia. However, as the edema resolves, the ducts and parenchyma return to normal.

In the setting of acute pancreatitis, the combined MRI and MRCP examinations assist in detecting the cause, extent, and complications of this inflammatory process. Pancreatic enlargement, simple and infected fluid collections, necrosis, thoracopancreatic fistulas, vascular thrombosis, and pseudoaneurysms are well depicted. In fact, MRI has been shown to perform well compared with CT in the evaluation of inflammation and necrosis and in the calculation of the severity index.⁶³ In one study, MRI was superior to CT and ultrasonography for detection of debris in subacute pancreatic fluid collections, an important factor in assessing drainability.⁶⁴

Therefore, an examination including both MRCP and MRI, and at times MRA, yields information about the pancreaticobiliary tract, pancreatic parenchyma, surrounding tissues, and vessels in a single, noninvasive examination that does not expose the patient to radiation or iodinated contrast material. The disadvantages of MRI in the setting of severe acute pancreatitis include the fact that MRI cannot be performed as rapidly as CT and that CT must be used for critically ill patients on ventilators.

CHRONIC PANCREATITIS

MRCP and MRI have emerged as useful tools in demonstrating the ductal and parenchymal manifestations of chronic pancreatitis.^{3,65} The ductal features include dilation of the main pancreatic duct and its side branches, mural irregularity, intraductal stones, and strictures of the pancreatic duct and the intrapancreatic bile duct (Fig. 75-15). A study comparing ERCP with

Figure 75-15 Chronic pancreatitis. **A.** Coronal thick-slab MRCP provides a comprehensive image of the pancreaticobiliary tract by demonstrating marked dilation of the main pancreatic duct (arrows) and its side branches and a tapered stricture of the intrapancreatic bile duct (arrowhead). **B.** Coronal oblique thin-slab MRCP focusing on the pancreatic body depicts the dilation of the main pancreatic duct (arrows), its dilated side branches (arrowheads), and rounded intrapancreatic pseudocysts. **C.** Coronal oblique thin-slab MRCP focusing on the pancreatic head demonstrates the smooth, tapered stricture of the intrapancreatic bile duct (arrowhead) that results in dilation of the suprapancreatic bile duct. Again noted are the intrapancreatic pseudocysts and the dilated pancreatic duct and its side branches.

MRCP revealed very good correlation between MRCP and ERCP findings but showed that both modalities failed to depict some abnormalities depicted by the other technique.⁶⁵ In another study including 36 patients with chronic pancreatitis, MRCP identified biliary strictures in 16 and correctly classified all as benign.³ MRCP provides accurate delineation of the ductal manifestations of chronic pancreatitis, which is of utmost importance in determining disease extent and in planning surgical drainage procedures. In some instances, MRCP demonstrates the ductal disease more completely than ERCP does because MRCP readily demonstrates ducts proximal to a high-grade stricture.

MRI is helpful in showing parenchymal manifestations of chronic pancreatitis, such as atrophy and fibrosis, as well as peripancreatic findings, such as pseudocysts. T1-weighted, fat-suppressed, unenhanced sequences are particularly useful in delineating fibrosis and atrophy that result in diminished signal intensity of the pancreas relative to the liver because of the replacement of aqueous protein in the pancreatic parenchyma.^{66,67} Pancreatic enhancement is reduced in patients with chronic calcific pancreatitis compared with

glands without calcifications.⁶⁶ This is presumably due to more severe disease.

Secretin-enhanced MRCP improves visualization of the morphologic features of chronic pancreatitis and can assist in determining function of the exocrine pancreas by assessing fluid output.^{8,68-70}

Gallbladder Diseases

Sonography is the initial modality used to evaluate the gallbladder as it is accurate, relatively inexpensive, readily available, rapidly performed, and portable. MRCP is useful in detecting abnormalities including gallstones, acute cholecystitis (Fig. 75-16), gangrenous cholecystitis, gallbladder perforation, Mirizzi syndrome, carcinoma, and adenomyomatosis (Fig. 75-17).^{3,71-73} In the setting of acute cholecystitis, MRCP coupled with MRI is useful in detecting bile duct stones and in demonstrating extension of infection from the gallbladder to the adjacent hepatic parenchyma. When gallbladder carcinoma is suspected, MRI used in conjunction with MRCP assists in staging.⁷²⁻⁷⁴

Figure 75-16 Acute cholecystitis complicated by a bile duct stone and hepatic abscess.

A. Axial HASTE image shows a distended gallbladder with a thick, irregular wall indicative of acute cholecystitis in this patient with right upper quadrant pain and leukocytosis.

B. Coronal oblique thin-slab MRCP shows a distal common bile duct stone (*arrow*). **C.** Axial, T1-weighted, fat-suppressed, enhanced MRI reveals an abscess (*arrow*) in the medial segment of the left hepatic lobe due to contiguous extension from the gallbladder.

Figure 75-17 Adenomyomatosis. MIP image shows the “pearl necklace” sign of adenomyomatosis that represents dilated Rokitsky-Aschoff sinuses (*arrows*). Artifactual narrowing of the proximal extrahepatic bile duct (*arrowhead*) is noted.

CHAPTER OUTLINE

Embryology

Agenesis of the Gallbladder

Duplication of the Gallbladder

Anomalies of Gallbladder Shape

Phrygian Cap

Multiseptate Gallbladder

Diverticula

Abnormalities of Gallbladder Position

Wandering Gallbladder

Gallbladder Torsion

Ectopic Gallbladder

Abnormalities in Gallbladder Size

Cholecystomegaly

Microgallbladder

Biliary Tract Anomalies

Choledochal Cysts

Choledochoceles

Caroli's Disease

There are many congenital abnormalities of the gallbladder and bile ducts, which, excluding biliary atresia and choledochal cysts, are usually of no clinical or functional significance.¹ These anomalies are usually found in the course of evaluating biliary disease in an adult patient and are of interest primarily to the surgeon, who must deal with the anatomic variation during the course of surgery.²⁻⁶

Embryology

When the human embryo is 2.5 mm in size, a bifid bud forms along the anterior margin of the primitive foregut and proliferates laterally into the septum transversum. The more cephalad of these two diverticula is responsible for the formation of the liver and intrahepatic bile ducts, whereas the caudal diverticulum develops into the gallbladder and extrahepatic biliary tree. At the 5-mm stage of development, the originally hollow primordium of the gallbladder and common bile duct becomes occluded with endodermal cells but is soon revacuolated. If recanalization is incomplete, a compartmentalized multiseptate gallbladder results. A single, transversely oriented septum results in the phrygian cap deformity, whereas longitudinal septa produce a bifid or triple gallbladder. The lumen of the common bile duct is reestablished at the 7.5-mm stage and the

gallbladder and duodenal lumen somewhat later. Bile is secreted by the 12th week.^{4,5}

At the 10- to 15-mm stage (6-7 weeks), the gallbladder has formed and is connected to the duodenum by a canalized choledochocystic duct. This duct originates from the lateral aspect of the primitive foregut and eventually terminates on the medial or posteromedial aspect of the descending portion of the duodenum after the foregut completes its 270-degree rotation.⁴⁻⁶

The formation of the intrahepatic ducts is preceded by the development of the portal and hepatic veins and the formation of the hepatocytes and Kupffer cells. The intrahepatic ducts by the 18-mm stage consist only of a blindly ending solid core of cells that extends from the junction of the cystic and common ducts toward the liver hilum. At the point of contact between this blindly ending ductal anlage and the hepatocytes, the intrahepatic ducts develop along the framework of the previously formed portal vein branches similar to vines on a trellis. Significant variation in the configuration of the intrahepatic ducts can be accounted for by the unpredictable manner in which they wind around pre-existing portal veins.⁴⁻⁶

Agenesis of the Gallbladder

Agenesis of the gallbladder is caused by failure of development of the caudal division of the primitive hepatic diverticulum or failure of vacuolization after the solid phase of embryonic development. Atresia or hypoplasia of the gallbladder also represents aborted development of the organ.⁷⁻⁹ Other congenital anomalies are present in two thirds of these patients, including congenital heart lesions, polysplenia, imperforate anus, absence of one or more bones, and rectovaginal fistula.¹⁰ There appears to be a genetic input as well because several families with multiple individuals having agenesis have been identified.¹⁰ This malformation is reported in 0.013% to 0.155% of autopsy series, but many of these cases are in stillborn and young infants. The surgical incidence of gallbladder agenesis is approximately 0.02%.^{10,11} Nearly two thirds of adult patients with agenesis of the gallbladder have biliary tract symptoms, and extrahepatic biliary calculi are reported in 25% to 50% of these patients.¹²⁻¹⁴

Preoperative diagnosis of gallbladder agenesis is difficult, and the absence of the gallbladder is often an intraoperative finding.^{2,8,14} Ultrasound or computed tomography (CT) may suggest the diagnosis, but this disorder is usually diagnosed at surgery when the gallbladder is not found at cholangiography.¹⁵ Intraoperative ultrasound may be helpful in establishing the diagnosis and excluding a completely intrahepatic gallbladder.¹⁶ Agenesis of the gallbladder is a rare cause of false-positive hepatobiliary scintiscans.¹⁷

Duplication of the Gallbladder

Gallbladder duplication occurs in about 1 in 4000 people and 4.8% of domestic animals.¹⁸⁻²⁰ This anomaly is caused by incomplete revacuolization of the primitive gallbladder, resulting in a persistent longitudinal septum that divides the gallbladder lengthwise. Another possible mechanism is the occurrence of separate cystic buds. To establish the diagnosis, two separate gallbladder cavities, each with its own cystic duct, must be present. These duplicated cystic ducts may enter the common duct separately or form a Y configuration before a common entrance.²¹

Most reported cases of gallbladder duplication have a clinical picture of cholecystitis with cholelithiasis in at least one of the gallbladders. Sometimes one of the gallbladders appears normal on oral cholecystography, whereas the second, diseased, nonvisualized, and unsuspected gallbladder produces symptoms.²²⁻²⁴

A number of entities can mimic the double gallbladder at sonography: folded gallbladder, bilobed gallbladder, choledochal cyst, pericholecystic fluid, gallbladder diverticulum, vascular band across the gallbladder, and focal adenomyomatosis.²⁵⁻²⁸ Complications associated with double gallbladder include torsion and the development of papilloma, carcinoma, common duct obstruction, and secondary biliary cirrhosis.²⁷ Treatment of this disorder consists of removal of both gallbladders.

Triple and quadruple gallbladders have also been reported.²⁸ Diverticular gallbladders without cystic ducts are classified as accessory gallbladders.

Anomalies of Gallbladder Shape

PHRYGIAN CAP

Phrygian cap is the most common abnormality of gallbladder shape, occurring in 1% to 6% of the population.²⁹ It is named after the headgear worn by ancient Greek slaves as a sign of liberation. This deformity is characterized by a fold or septum of the gallbladder between the body and fundus. Two variations of this anomaly have been described. In the retroserosal or concealed type, the gallbladder is smoothly invested by peritoneum, and the mucosal fold that projects into the lumen may not be visible externally. In the serosal or visible type, the peritoneum follows the bend in the fundus, then reflects on itself as the fundus overlies the body. This anomaly is of no clinical significance unless it is mistaken for a layer of stones or hyperplastic cholecystosis.^{3,15,24-29}

MULTISEPTATE GALLBLADDER

The multiseptate gallbladder is a solitary gallbladder characterized by multiple septa of various sizes internally and a faintly bosselated surface externally.²⁸⁻³⁰ The gallbladder is usually normal in size and position, and the chambers communicate with one another by one or more orifices from fundus to cystic duct. These septations lead to stasis of bile and gallstone formation.³¹ On ultrasound studies, multiple communicating septations and locules are seen bridging the gallbladder lumen.³² Oral cholecystography reveals the "honeycomb" multicystic character of the gallbladder. The sonographic

differential diagnoses are desquamated gallbladder mucosa and hyperplastic cholecystoses.

DIVERTICULA

Gallbladder diverticula are rare and usually clinically silent. They can occur anywhere in the gallbladder and are usually single and vary greatly in size. Congenital diverticula are true diverticula and contain all the mural layers, as opposed to the pseudodiverticula of adenomyomatosis, which have little or no smooth muscle in their walls. Acquired traction diverticula from adjacent adhesions or duodenal disease must also be excluded.^{7,8,15}

Abnormalities of Gallbladder Position

WANDERING GALLBLADDER

When the gallbladder has an unusually long mesentery, it can "wander" or "float."³³⁻³⁷ The gallbladder may "disappear" into the pelvis on upright radiographs or wander in front of the spine or to the left of the abdomen. Rarely, the gallbladder can herniate through the foramen of Winslow into the lesser sac. In these cases, cholecystography reveals an unusual angulation of the gallbladder, which lies parallel and adjacent to the duodenal bulb with its fundus pointing to the left upper quadrant. The herniation can be intermittent and may be responsible for abdominal pain. It is best seen by a barium meal in conjunction with oral cholecystography. Cross-sectional imaging may not be specific, showing only a cystic structure in the lesser sac.

GALLBLADDER TORSION

Three unusual anatomic situations give rise to torsion of the gallbladder, and they all produce twisting of an unusually mobile gallbladder on a pedicle: (1) a gallbladder that is completely free of mesenteric or peritoneal investments except for its cystic duct and artery, (2) a long gallbladder mesentery sufficient to allow twisting, and (3) the presence of large stones in the gallbladder fundus that cause lengthening and torsion of the gallbladder mesentery. Kyphosis, vigorous gallbladder peristalsis, and atherosclerosis have also been implicated as other predisposing or contributing factors.³⁸ The mesentery is sufficiently long to permit torsion in 4.5% of the population. Most cases of gallbladder torsion occur in women (female-to-male ratio of 3:1).³⁹ The usual preoperative diagnosis is acute cholecystitis. The presence of fever is variable, leukocytosis is common, and one third of patients have a right upper quadrant mass. Gangrene develops in more than 50% of cases and is extremely common when the pain has been present for more than 48 hours. On cross-sectional imaging, the gallbladder is distended and may have an unusual location and show mural thickening. The diagnosis is seldom made preoperatively, however.^{40,41}

ECTOPIC GALLBLADDER

The gallbladder can be located in a variety of anomalous positions. In patients with an intrahepatic gallbladder, the gallbladder is completely surrounded by hepatic parenchyma. The intrahepatic gallbladder usually presents little difficulty in imaging, but it may complicate the clinical diagnosis of acute

Figure 76-1 Gallbladder ectopia.

A. Intrahepatic gallbladder (GB) demonstrated on CT scan. **B.** Retrohepatic gallbladder shown on an oral cholecystogram. **C.** Situs inversus with left-sided gallbladder.

cholecystitis because of a paucity of peritoneal signs resulting from the long distance between the gallbladder and peritoneum. This anomaly also makes cholecystectomy more difficult. On sulfur colloid scans, the intrahepatic gallbladder presents as a cold hepatic defect.

The gallbladder has also been reported in the following positions: suprahepatic, retrohepatic (Fig. 76-1), supradiaphragmatic, and retroperitoneal. In patients with cirrhosis, small or absent right lobes, or chronic obstructive pulmonary disease, the gallbladder together with the colon is often interposed between the liver and the diaphragm.⁴² Left-sided gallbladders may occur in situs inversus or as an isolated finding. They can also lie in the falciform ligament, transverse mesocolon, and anterior abdominal wall.

Abnormalities in Gallbladder Size

CHOLECYSTOMEGALY

Enlargement of the gallbladder has been reported in a number of disorders including diabetes (because of an autonomic neuropathy) and after truncal and selective vagotomy. The gallbladder also becomes larger than normal during pregnancy, in patients with sickle hemoglobinopathy, and in extremely obese people.⁴³⁻⁴⁶

MICROGALLBLADDER

In patients with cystic fibrosis, the gallbladder is typically small, trabeculated, contracted, and poorly functioning. It often

contains echogenic bile, sludge, and cholesterol gallstones. These changes are presumably due to the thick, tenacious bile that is characteristic of this disease.^{47,48}

Biliary Tract Anomalies

Anomalies of the biliary system are found in 2.4% of autopsies, 28% of surgical dissections, and 5% to 13% of operative cholangiograms.⁶ The most common anomaly is an aberrant intrahepatic duct draining a circumscribed portion of the liver, such as an anterior or posterior segment right lobe duct that drains into the left main rather than the right main hepatic duct. The aberrant main can join the common hepatic duct, common bile duct, or cystic duct or insert into a low right hepatic duct. Rarely, it may run through the gallbladder fossa or into the gallbladder, predisposing it to injury at cholecystectomy.

The hepatic ducts may join either higher or lower than normal. Surgical difficulties may arise when the cystic duct enters into a low inserting right hepatic duct or when the right hepatic duct enters into the cystic duct before joining the left hepatic duct. Duplications of the cystic duct and common bile duct are rare. Anomalies of cystic duct insertion occur as well (Fig. 76-2).

Congenital tracheobiliary fistula is a rare disorder that is manifested with respiratory distress and cough with bilious sputum. The fistula begins near the carina, traverses the diaphragm, and usually communicates with the left hepatic duct. Pneumobilia may be seen on plain radiography, and the diagnosis is confirmed with biliary scintigraphy.

Figure 76-2 Anatomic variants in the cystic duct. Drawings illustrate how the cystic duct may insert into the extrahepatic bile duct with a right lateral insertion (A), anterior spiral insertion (B), posterior spiral insertion (C), low lateral insertion with a common sheath (D), proximal insertion (E), or low medial insertion (F). (From Turner MA, Fulcher AS: *The cystic duct: Normal anatomy and disease processes*. RadioGraphics 21:3–22, 2001.)

Choledochal cysts, choledochoceles, and Caroli's disease are a part of a spectrum of biliary anomalies that produce dilation of the biliary tree. They are discussed individually in the following section, and their relationship is illustrated in Figure 76-3.

CHOLEDOCHAL CYSTS

Choledochal cysts (Figs. 76-4 to 76-6) are congenital cystic dilations of any portion of the extrahepatic bile ducts, most commonly the main portion of the common bile duct.^{49–55} It is postulated that this condition begins with an anomalous junction of the common bile duct and pancreatic duct proximal to the duodenal papilla. Higher pressure in the pancreatic duct combined with an absent ductal sphincter allows free reflux of enzymes into the biliary tree, weakening the wall of the common bile duct. There is a 3:1 female predominance, and 60% of patients present before the age of 10 years, although choledochal cysts can present from birth to old age. This anomaly is associated with an increased incidence of gallbladder anomalies, other biliary anomalies (e.g., biliary stenosis or atresia), and congenital hepatic fibrosis. Complications of choledochal cysts in adults include rupture with bile peritonitis, secondary infection (cholangitis), biliary cirrhosis and portal hypertension, calculus formation, portal vein thrombosis, liver abscess, hemorrhage, and malignant transformation into cholangiocarcinoma.^{55–57}

Figure 76-3 Classification of choledochal cysts.

Figure 76-4 Type I choledochal cysts. **A.** Coronal oblique multiplanar reformatted CT image shows fusiform dilation of the common bile duct (arrow). Note also the dilation of the intrahepatic biliary tract (arrowhead). **B.** Percutaneous transhepatic cholangiogram in the same patient shows a large choledochal cyst (c) at the level of the extrahepatic bile duct. Note the aberrant entry of the common bile duct at the side of the pancreatic duct (arrowhead). **C.** MRCP in a different patient shows a dilated main common bile duct.

Figure 76-5 Type III choledochal cyst: choledochoceles. **A.** ERCP shows saccular dilation of the distal common bile duct (c) and choledocholithiasis (arrow). **B.** Coronal MRCP image demonstrates bulbous dilation of the intramural segment of the distal common bile duct (arrows), which protrudes into the duodenum (D).

Newborns and infants present with obstructive jaundice.^{54,55} Older children and adults may have the classic triad of right upper quadrant pain, intermittent jaundice, and a palpable right upper quadrant mass. In adult patients, a choledochal cyst is often first diagnosed on cross-sectional imaging. CT (see Fig. 76-4) and ultrasound demonstrate a fluid-filled structure beneath the porta hepatis separate from the gallbladder that communicates with the hepatic ducts. An abrupt change in the caliber of the ducts occurs at the site of the cysts. Intrahepatic ductal dilation may be present as well.

Cholangiography is necessary to confirm the diagnosis. It demonstrates a cystic structure 2 to 15 cm in diameter that communicates with the hepatic ducts. An abrupt change in ductal caliber occurs at the site of the cyst. Mild intrahepatic ductal dilation, stones, or sludge may be present as well. Cholangiography is useful for fully defining ductal anatomy.

Upper gastrointestinal series may show a soft tissue mass in the right upper quadrant that causes anterior displacement of the second portion of the duodenum and antrum or inferior

Figure 76-6 Type IV choledochal cyst. MRCP image shows massive dilation of the common bile duct (CBD) as well as the right (RHD) and left (LHD) intrahepatic ducts. GB, Gallbladder.

displacement of the duodenum or widening of the duodenal sweep.⁵⁴⁻⁵⁶

Ultrasound findings reflect the specific type of choledochal cyst, although a cystic extrahepatic mass is typically present. A portion of the proximal bile duct can often be seen extending into the choledochal cyst. Hepatobiliary scans show late filling and stasis of the isotope within the choledochal cyst.⁵³ They are useful in excluding hepatic cyst, pancreatic pseudocyst, and enteric duplication.

Direct coronal magnetic resonance (MR) imaging demonstrates a dilated tubular structure that follows the expected course of the common bile duct. MR cholangiopancreatography (MRCP) can also demonstrate these dilated biliary structures because the luminal contents of the bile appear hyperdense in contrast to the portal vein. MRCP can also diagnose biliary calculi and stricture formation that frequently complicate cystic disease of the bile ducts. Two studies showed that MRCP offered equivalent information to endoscopic retrograde cholangiopancreatography (ERCP), without the potential complications inherent in the latter procedure. In patients with choledochal cysts who are reluctant to undergo surgical resection, periodic follow-up ultrasound and MRCP may help achieve early detection of malignant change.⁵² The management of choledochal cysts is surgical, with excision of all cyst tissue and reconstruction of continuity between the liver and gut by a Roux-en-Y hepaticojejunostomy.⁵⁷

CHOLEDOCHOCES

A choledochocoele is a rare, easily overlooked anomaly of unknown cause. This anomaly has been called variously an intraduodenal choledochal cyst, duodenal duplication cyst, diverticulum of the common bile duct, and enterogenous cyst of the duodenum. It is a protrusion of a dilated intramural segment of common bile duct into the duodenum, analogous

to a ureterocele.⁵⁸⁻⁶⁰ It is often seen on cholangiograms in patients who have had a cholecystectomy, so that the lesion may be partly acquired.

Choledochoceles usually are manifested in adulthood with long-standing nausea, vomiting, and episodic abdominal pain. Stones and sludge are often present, and patients often have episodes of biliary colic, intermittent jaundice, and pancreatitis as well.^{54,55}

Cholangiography shows smooth clublike or saclike dilation of the intramural segment of the common bile duct (see Fig. 76-5A). Barium studies demonstrate a smooth, well-defined intraluminal duodenal filling defect in this region of the papilla that changes in shape with compression and peristalsis. In contrast to intraluminal diverticula, choledochoceles do not fill with barium.⁵⁸⁻⁶⁰ On MRCP images, they have a high signal intensity, “cobra-head” appearance bulging into the duodenum (see Fig. 76-5B).

CAROLI'S DISEASE

Caroli's disease, also known as communicating cavernous ectasia, is characterized by multifocal segmental saccular dilation of the intrahepatic bile ducts, a predisposition to biliary calculi and cholangitis, and an association with various forms of cystic renal disease. Caroli's disease usually is manifested in adulthood; however, it can be seen in newborns and infants. Adult patients present with recurrent attacks of cholangitis and crampy right upper quadrant pain with occasional fever and mild jaundice. Infants and children may present with hematemesis caused by portal hypertension from hepatic fibrosis.^{54,55,61-63} This disease appears to be autosomal recessively inherited in most cases. Complications of Caroli's disease include stone formation (95%) within the dilated intrahepatic ducts, recurrent cholangitis, and liver abscess. There is also a 100-fold increase in the incidence of bile duct carcinoma, occurring in 7% of patients.

Caroli's disease is best demonstrated by cholangiography (Fig. 76-7), which shows saccular dilations of the intrahepatic ducts, stones, strictures, and communicating hepatic abscesses. CT can also demonstrate tiny dots with strong contrast enhancement within dilated intrahepatic bile ducts (the central dot sign). These intraluminal dots correspond to intraluminal portal veins.⁶⁴⁻⁶⁸ CT and ultrasound demonstrate multiple cystic areas within the liver.⁶⁹⁻⁷¹ (Fig. 76-8). Technetium Tc 99m sulfur colloid scans show multiple cold defects, and hepatobiliary scans show an unusual pattern of retained activity throughout the liver.^{54,55}

MRCP with three-dimensional display is an accurate method for demonstrating Caroli's disease because the luminal contents of the bile ducts appear hyperintense in contrast to the portal vein, which usually appears as signal void. Cystic expansions of the intrahepatic biliary tract are depicted as oval structures in continuity with the biliary tract (Fig. 76-9). They are nearly signal void on black bile techniques and have a high signal intensity on bright bile or MRCP sequences.⁷²

Treatment depends on the clinical features and location of the biliary abnormality. When the disease is localized to one hepatic lobe, hepatectomy relieves symptoms and appears to remove the risk of malignancy. In diffuse Caroli's disease, treatment options include conservative or endoscopic therapy, internal biliary bypass procedures, and liver transplantation in carefully selected cases.

Figure 76-7 Caroli's disease: cholangiographic findings. ERCP demonstrates bulbous dilations of the peripheral intrahepatic biliary radicles characteristic of Caroli's disease. (From Taylor AJ, Bohorfoush AG: *Interpretation of ERCP with Associated Digital Imaging*. Philadelphia, Lippincott-Raven, 1997, p 52, with permission.)

Figure 76-8 Caroli's disease: CT findings. The dilated segments of the intrahepatic biliary tract may be visualized as "cysts" (straight arrows), which are occasionally attached to more proximal ectatic segments of the biliary radicles (curved arrow). The defining CT feature of Caroli's disease is the central dot sign (open arrow). There is ectasia of the distal nephrons in the kidneys. (From Taylor AJ, Bohorfoush AG: *Interpretation of ERCP with Associated Digital Imaging*. Philadelphia, Lippincott-Raven, 1997, p 52, with permission.)

Figure 76-9 Caroli's disease: MR findings. **A.** Portal venous phase contrast enhanced T1 gradient echo axial image shows scattered cystic dilated intrahepatic bile ducts, some leading into mildly dilated ducts (arrow). Also present is the low signal intensity dilated duct surrounding the enhanced portal vein radicle forming the "central dot sign" (arrowhead). **B.** Coronal T2-weighted image shows multiple saccular dilatation of the intrahepatic biliary tree some demonstrating a connection with the more normal diameter ducts (arrows). **C.** Coronal T2-weighted MRI more posteriorly located in this patient with the intrahepatic cystic ductal changes of Caroli's disease shows cystic change in both kidneys (arrows). Also present is an enlarged spleen as a manifestation of portal hypertension, which has developed in this patient.

Gallbladder Hydrops

This chapter provides a review of the imaging assessment of gallbladder and biliary calculi. Cholecystitis, both acute and chronic, and associated complications are discussed. Other disorders related to gallstones, including spilled gallstones after laparoscopic surgery, Mirizzi syndrome, and gallstone ileus, are also reviewed. The chapter concludes with a discussion of the spectrum of noninflammatory gallbladder conditions referred to as the hyperplastic cholecystoses.

The imaging evaluation of cholelithiasis and associated complications has evolved significantly in the past decade. Cholescintigraphy and sonography continue to serve as the primary imaging modalities for the initial assessment of most suspected gallbladder disorders. Computed tomography (CT) and magnetic resonance imaging (MRI), however, have proved to be of considerable value in certain circumstances. These may be performed for initial evaluation or serve as an important adjunct to other imaging modalities when further information is required. The role of CT and MRI in the evaluation of cholecystitis, choledocholithiasis, and the hyperplastic cholecystoses is discussed.

Cholelithiasis

PATHOGENESIS AND EPIDEMIOLOGY

The prevalence of gallstones varies with age and gender. Gallstones are present in an estimated 10% to 15% of men and 20% to 40% of women older than 60 years.¹ In general, the risk for stones increases with history of childbearing, estrogen replacement therapy, oral contraceptive use, and obesity. Stones are also associated with hypertriglyceridemia, Crohn's disease, and parenteral hyperalimentation. Gallstones are symptomatic in 20% to 30% of patients; biliary pain or colic is the most common symptom. This is most often related to impaction of a stone in the cystic duct. The most common acute complications of gallstones are acute cholecystitis, acute pancreatitis, and ascending cholangitis. Chronic complications include chronic cholecystitis, Mirizzi syndrome, cholecystenteric fistula, and gallstone ileus.

Gallstones are composed mainly of cholesterol, bilirubin, and calcium salts with smaller amounts of protein and other

materials, including bile acids, fatty acids, and inorganic salts.² Stones form when there is supersaturation of various bile components. Lithogenic bile usually results from increased biliary cholesterol output, but decreased bile acid synthesis or a combination defect may play a role in stone development.¹ Biliary dysmotility and prolonged intestinal transit may also be contributing factors.³

In Western countries, cholesterol is the principal constituent of more than 75% of gallstones. Many stones are more than 80% cholesterol with smaller amounts of calcium bilirubinate. Pure cholesterol stones contain more than 90% cholesterol and are relatively uncommon, accounting for less than 10% of biliary calculi.² Pigment stones contain less than 25% cholesterol and are relatively uncommon, representing 10% to 25% of gallstones in North America.⁴ These stones consist of calcium salts of bilirubin and are categorized as black or brown pigment stones. Black pigment stones consist of polymers of bilirubin with large amounts of mucin glycoproteins. These are more common in patients with cirrhosis or chronic hemolytic anemias in whom biliary excretion is increased. Brown pigment stones are made up of calcium salts of unconjugated bilirubin, with variable amounts of protein and cholesterol, and are more commonly associated with bacterial infection. The deconjugation of bile by bacterial enzymes is also considered an etiologic factor.

IMAGING

Abdominal Radiography

Only about 15% to 20% of gallstones are calcified enough to be visualized on conventional abdominal radiographs⁵ (Fig. 77-1). Therefore, abdominal radiographs have a limited role in the detection of gallstones. Oral cholecystography was introduced in the 1920s and for many years was the primary modality for evaluation of gallbladder disease, including stones. However, this technique has largely been replaced by sonography.

Ultrasound

Sonography is now considered the imaging tool of choice for the detection of gallstones, with a reported accuracy of 96%.⁵⁻⁷ However, recent advances in sonographic technology resulting in improved spatial resolution may allow even higher diagnostic accuracy. Other advantages of sonography include the ability to perform studies at the bedside and lack of ionizing radiation. Sonography can also evaluate other structures in the right upper quadrant when alternative diagnoses are under consideration.

At sonography, a gallstone appears as a highly reflective echo that is generally mobile and associated with posterior acoustic shadowing (Fig. 77-2). Both mobility and acoustic shadowing are important features that help differentiate gallstones from other echogenic foci in the gallbladder lumen, such as sludge or solid masses. An aggregate of sludge or sludge ball (also referred to as tumefactive sludge) may be mobile but will not cast an acoustic shadow (Fig. 77-3). A solid mass will not be mobile and will not shadow and may exhibit vascularity on color Doppler interrogation.

Very small stones may not always cast a shadow. Ex vivo studies have demonstrated that calculi larger than 3 mm produce acoustic shadowing regardless of composition.^{8,9} The demonstration of a posterior acoustic shadow, however, also depends on transducer frequency and beam width. In a study

Figure 77-1 Gallstones: abdominal radiograph. Multiple calcified gallstones are identified.

by Grossman,¹⁰ when a 5-MHz transducer was used, 0.2- to 0.3-cm stones were associated with shadowing, whereas when a 2.25-MHz transducer was used, only stones measuring at least 0.4 cm cast a shadow. Using a tissue phantom, Filly and associates⁹ found that acoustic shadowing was present when the stone was at or near the center of the beam but not at the periphery. These studies demonstrate that to maximize detection, the highest frequency transducer possible should be used with the focal zone placed at the level of the stone. In recent years, tissue harmonic imaging has been shown to improve the detection rate of gallbladder calculi^{11,12} (Fig. 77-4).

Gallstones may not be detected at sonography if they are small or hidden behind a gallbladder fold or in the cystic duct, if intraluminal sludge is present, or if the examination is technically suboptimal related to the patient's body habitus or the operator's inexperience. Chintapalli and colleagues¹³ studied 946 patients with surgically proved gallstones. In 98.7%, preoperative sonography showed single or multiple echogenic foci with or without acoustic shadowing in the gallbladder for a false-negative rate of 1.3%. In the patients with false-negative examinations, sonographic findings were consistent with polyps (five cases), sludge, or both, and the ultrasound was interpreted as normal in one patient. Missed stones were 5 mm or smaller in 10 patients and smaller than 1.0 cm in all 12 patients. Stones located in the gallbladder neck or trapped behind a fold may be overlooked when the patient is evaluated only in the supine position. Also, small stones may become more conspicuous when the patient is evaluated in the decubitus or upright position as they produce a shadow only when they are imaged in

Figure 77-2 Gallstones: sonography. **A.** Two highly reflective echoes (arrows) are located in the dependent portion of the gallbladder lumen with posterior acoustic shadowing (arrowheads). **B.** When the patient is imaged in the left lateral decubitus position (LLD), the gallstones (arrows) change location, indicating mobility.

aggregate (Fig. 77-5). Therefore, it is always important to evaluate the patient in more than one position in assessing for the presence of gallstones. A follow-up study may be suggested if the clinical index of suspicion is high and the initial examination is negative.

If the gallbladder is contracted and the lumen is filled with shadowing stones, a high-amplitude echo results that is usually linear or curvilinear in configuration and associated with posterior acoustic shadowing. Careful observation will demonstrate a perceivable gallbladder wall separate from the intraluminal stones, sometimes facilitated by the use of a high-resolution linear transducer (Fig. 77-6). This appearance has been called the wall-echo-shadow sign.¹⁴ The main differential diagnostic considerations are a porcelain gallbladder, with calcification in the gallbladder wall, and air in the gallbladder, such as in emphysematous cholecystitis. Correlation with abdominal radiography or CT can be helpful as a problem-solving tool (Fig. 77-7).

Computed Tomography

The ability to detect gall stones at CT depends on differing density of the stone with respect to bile.^{15,16} The reported sensitivity of CT for detection of gallstones is approximately 75%.¹⁷ Calcified stones are readily identified as they are denser than bile (Fig. 77-8A). Stones with high concentration of cholesterol may also be readily identified as these stones are less dense than bile (Fig. 77-8B). When stones degenerate, nitrogen gas may collect in central fissures and create the Mercedes-Benz sign. This may be the only visualized evidence of a gallstone and appear as a focal collection of gas in the nondependent gallbladder lumen (Fig. 77-8C). Noncalcified pigment stones are soft tissue attenuation density (Fig. 77-8D). Many stones are composed of a mixture of calcium, bile pigments, and cholesterol and may be similar in density to bile and therefore not visible at CT (Fig. 77-9). The size of the stone is also an important factor determining if a stone is visible at CT. Small stones are frequently missed unless the density differs markedly from bile. In one series, only 78.9% of patients with stones demonstrated at sonography were found to have stones at CT.¹⁸ Most stones missed prospectively were faintly calcified and were retrospectively detected only as subtle defects within the gallbladder. A phantom study demonstrated that the sensitivity of CT for

Figure 77-3 Tumefactive sludge: sonography. **A.** In the supine position, there is an echogenic nonshadowing focus (arrow) in the dependent portion of the gallbladder lumen. There is no posterior acoustic shadowing. **B.** In the upright position, the sludge ball moved into the gallbladder fundus (arrow).

Figure 77-4 Gallstones: improved sonographic visualization with tissue harmonic imaging. **A.** Image obtained with 4-MHz transducer demonstrates gallstones (arrow). Near-field echoes (arrowhead) correspond to reverberation artifact. **B.** Image obtained with tissue harmonic imaging eliminates reverberation artifact. Gallstones are better delineated (arrow), and posterior acoustic shadowing is more evident (arrowhead).

Figure 77-5 Gravel: sonographic appearance. **A.** Supine scan of the gallbladder (g) demonstrates echogenic layering material in the lumen (arrow) with no posterior acoustic shadowing. **B.** In the decubitus position, the material pools in the fundus of the gallbladder (arrow), and a shadow is now demonstrated (arrowhead) consistent with small stones or gravel.

Figure 77-6 Wall-echo-shadow sign on ultrasound. Multiple gallstones are present within a contracted gallbladder. Sagittal (**A**) and transverse (**B**) views. Short arrow points to gallbladder wall that appears as an echogenic arc. Long arrow points to gallstones that appear as bright echoes. The arrowhead points to posterior acoustic shadowing.

detection of gallstones varies with peak voltage and is highest when CT is performed at 140 kVp rather than at lower voltage settings.¹⁹

Magnetic Resonance Imaging

On T2-weighted MRI, gallstones are manifested as signal voids in the high signal intensity bile (Fig. 77-10). Cholesterol stones are generally isointense or hypointense on T1-weighted images, whereas pigment stones have been shown to have high signal intensity on T1-weighted images. This signal hyperintensity is

caused by the presence of metal ions in the pigment stones, shortening the T1 relaxation time.^{20,21} Another study of gallstone appearance at MRI also correlated signal intensity with chemical composition.²² T2-weighted central high signal intensity corresponded to fluid-filled clefts in the stones, whereas central and peripheral high signal areas on T1-weighted images corresponded to fluid clefts as well as regions high in copper content. Other intraluminal filling defects that may mimic gallstones on T2-weighted images include tumor, blood clot, and gas bubbles.

Figure 77-7 Porcelain gallbladder: imaging features. **A.** Ultrasound demonstrates increased echogenicity of the wall (arrow) of the gallbladder (g). **B.** CT scan shows concentric mural calcification of the gallbladder (g), confirming porcelain gallbladder. **C.** Abdominal radiograph shows concentric mural calcification.

Biliary Sludge

PATHOGENESIS

Biliary sludge, also referred to as microlithiasis, biliary sand or sediment, pseudolithiasis, and microcrystalline disease, is a suspension of bile and particulate material in the gallbladder.²³ The chemical composition consists of various proportions of calcium bilirubinate and cholesterol monohydrate crystals and gallbladder mucus. The proposed pathogenesis is similar to that of gallstones. A combination of impaired gallbladder motility and alteration in nucleation factors leads to the formation of sludge, with additional precipitate aggregation resulting in gallstone formation.²⁴ Clinical conditions that increase sludge formation include fasting, pregnancy, total parenteral nutrition, and critical illness. Sludge may resolve, have a cyclic pattern of appearance and disappearance, or progress to stone formation.²⁵ Although patients may generally be asymptomatic, symptoms can include biliary pain, cholecystitis, cholangitis, or pancreatitis. Treatment is symptom directed.

IMAGING

At sonography, sludge typically appears as low-level echoes that layer dependently within the gallbladder lumen (Fig. 77-11).

When the gallbladder lumen is entirely filled with sludge, this yields an appearance referred to as hepatization of the gallbladder. In this situation, the gallbladder assumes the same echotexture as the liver parenchyma (Fig. 77-12A, B). The use of color Doppler imaging is important to exclude other more significant disease, such as intraluminal soft tissue masses. If findings are equivocal and there is suspicion for a possible intraluminal mass, MRI with contrast and subtraction images can be helpful (Fig. 77-12C, D). An aggregate of intraluminal sludge can also mimic a soft tissue density mass (tumefactive sludge). As discussed, gravity dependence should be demonstrated to differentiate sludge from a gallbladder polyp or mass (Fig. 77-13). Doppler demonstration of vascularity within the abnormality confirms the presence of a soft tissue mass. However, absence of demonstrable vascularity is less helpful, and short-interval follow-up examination or assessment with precontrast and postcontrast CT or MRI may be indicated.

Acute Cholecystitis

PATHOGENESIS AND EPIDEMIOLOGY

Acute cholecystitis occurs in approximately one third of patients with gallstones. It results from persistent obstruction of the

Figure 77-8 CT appearance of gallstones. **A.** Calcified stones depicted as calcified dependent densities in gallbladder lumen (arrow). **B.** Noncalcified stones may be visible if they are less dense than bile (arrows). This patient also had acute cholecystitis. Note thickened gallbladder wall (arrowhead). **C.** Mercedes-Benz sign. Gas-containing stone floating in bile (arrow). **D.** Pigment stone (arrow) is soft tissue density with only small central nidus of calcification.

Figure 77-9 Noncalcified gallstones not visualized at CT. **A.** CT scan demonstrates no stones in the gallbladder (g). **B.** Ultrasound performed immediately after CT demonstrates shadowing stone (arrow) in gallbladder (g) lumen. **C.** CT scan in a different patient demonstrates no stones in the gallbladder. **D.** CT performed several days later in the same patient now demonstrates multiple stones in the gallbladder because of vicarious excretion of previously administered intravenous contrast material in the gallbladder.

Figure 77-10 MRI appearance of gallstones. Axial T2-weighted HASTE image demonstrates multiple low signal intensity filling defects in gallbladder lumen (arrow).

cystic duct or gallbladder neck, with distention of the gallbladder and increased intraluminal pressure.^{26,27} Inflammation of the gallbladder mucosa may result from chemical injury caused by bile salts or superimposed infection. If left untreated, the inflammation eventually progresses to involve all layers of the gallbladder wall and may lead to necrosis, gangrene, and gallbladder perforation. In most patients, acute cholecystitis is associated with gallstones.

Acute cholecystitis is the most common cause of right upper quadrant pain, and the primary mode of treatment is laparoscopic cholecystectomy. Clinical findings include fever, right upper quadrant pain, and elevated white blood cell count. Approximately one third of patients have a clinically positive Murphy sign, which refers to focal tenderness over the gallbladder on inspiration. However, the clinical manifestations may overlap considerably with other intra-abdominal processes not related to the biliary tract, such as acute hepatitis, primary liver disease including abscess and neoplasm, peptic ulcer disease, and pancreatitis. Also, clinical findings in the elderly or critically ill patient may be more subtle. Approximately one third of patients with the presumptive diagnosis of acute cholecystitis will not have acute cholecystitis on follow-up, and 20% to 25% of patients who have surgery for acute cholecystitis will ultimately have a different diagnosis.²⁸ In a series of 52 patients with right upper quadrant pain thought to have acute cholecystitis, acute cholecystitis was confirmed in 34.6%, chronic cholecystitis was confirmed in 32.7%, and 32.7% had normal gallbladders.²⁹ Therefore, imaging evaluation is critical to provide prompt diagnosis and appropriate intervention.

In 2007, the Tokyo Guidelines that describe the diagnostic and severity assessment criteria for acute cholecystitis were published, and these were recently updated in 2013.^{30,31} According to these guidelines, the diagnostic criteria for acute cholecystitis are one local sign of inflammation (Murphy sign; mass, pain, or tenderness in right upper quadrant), one systemic sign of inflammation (fever, elevated C-reactive protein level,

Figure 77-11 Sludge: sonographic findings. **A.** Ultrasound shows low-level, nonshadowing intraluminal echoes (s). **B.** Color Doppler shows no vascularity in sludge (s), helping to exclude a solid, intraluminal mass.

elevated white blood cell count), and confirmatory imaging findings. Cholecystitis severity is classified as mild, moderate, or severe (stages I, II, III, respectively). Mild cholecystitis is defined as cholecystitis with mild inflammatory changes adjacent to the gallbladder without organ dysfunction. Moderate cholecystitis includes elevated white blood cell count, palpable tender mass in the right upper quadrant, duration of symptoms longer than 72 hours, and marked local inflammation. Severe cholecystitis is defined as cholecystitis combined with multiple organ dysfunction. Radiologic findings may have an important impact on how a patient with acute cholecystitis is treated once the diagnosis is established. In a patient with sepsis and organ failure, percutaneous drainage with delayed cholecystectomy may be the best option. Patients without severe inflammation may be best managed with early laparoscopic cholecystectomy. Up to 30% of patients treated laparoscopically may undergo conversion to an open procedure, usually in the setting of severe complicated cholecystitis with dense pericholecystic inflammation and adhesions. Preoperative imaging may also help predict which patients are likely to require conversion to an open procedure.³²

Figure 77-12 Sludge-filled gallbladder: sonography and MR features. Sagittal (A) and transverse (B) sonograms demonstrate gallbladder lumen (g) filled with echogenic material. The echotexture is similar to that of the adjacent liver parenchyma (h). This appearance is referred to as hepatization of the gallbladder. C. Coronal T2-weighted HASTE MR image demonstrates intermediate signal intensity material in the gallbladder lumen (g). D. Axial contrast-enhanced T1-weighted fat-suppressed MR image with subtraction shows no enhancement of gallbladder lumen (g), excluding an intraluminal mass.

IMAGING

The relative role of ultrasonography versus cholescintigraphy with technetium-tagged iminodiacetic acid (IDA) and IDA-like agents for the diagnosis of acute cholecystitis has been extensively addressed in the literature. In an early study published in 1982, the accuracy of scintigraphy with IDA compared with sonography showed similar excellent results in 91 patients with suspected acute cholecystitis, with accuracy of ultrasound of 88% and of scintigraphy of 85%.³³ A study in 1983 of 194 patients showed that sensitivity of both modalities was high, but the specificity of ultrasound was lower at 64%, with a positive predictive value of 40%.³⁴ The sonographic Murphy sign, however, was not evaluated in this study, and there was no correlation with clinical data. More recent studies comparing cholescintigraphy and sonography for diagnosis of acute cholecystitis showed an accuracy of scintigraphy of 91% versus 77% for sonography and sensitivity of scintigraphy of 90.9% versus 62% for ultrasound.^{35,36} Most recently, a systematic review and meta-analysis of diagnostic performance of imaging in acute cholecystitis was performed.³⁷ Fifty-seven studies were included with evaluation of 5859 patients. The sensitivity and specificity were 96% and 90% for cholescintigraphy compared with 81% and 83% for ultrasound.

Although it is possibly somewhat less sensitive and specific for the diagnosis of acute cholecystitis compared with cholescintigraphy, ultrasound does have the advantages of being

readily available and rapidly performed, involving no radiation, and allowing detection of cholecystitis-related complications as well as alternative diagnoses. Ultrasound can confirm the diagnosis of acute cholecystitis and distinguish it from chronic cholecystitis with an accuracy of 95% to 99%.²⁶ The disadvantages of radionuclide scintigraphy include the time to perform the examination (up to 4 hours) and the inability to evaluate for nonbiliary conditions. Furthermore, false-positive results can occur in patients with high bilirubin levels and severe intercurrent illnesses. False-negative results, however, are rare.

Depending on the clinical circumstances, a combination of both cholescintigraphy and sonography may be required to make a definitive diagnosis of acute cholecystitis. The American College of Radiology appropriateness criteria for evaluation of patients with right upper quadrant pain, most recently updated in 2010,²⁸ score ultrasound higher than cholescintigraphy for evaluation of the patient with fever, elevated white blood cell count, and positive Murphy sign and state that cholescintigraphy should generally follow ultrasound on the basis of ultrasound findings. If there is pain but no fever or leukocytosis, ultrasound is given the highest score and may allow detection of stones and bile duct obstruction. If there are only gallstones and pain, cholescintigraphy, CT, and MRI are given equal scores. CT and MRI may allow detection of other causes of pain, improved detection of choledocholithiasis, and further evaluation when it is required, such as when complications are suspected (discussed further later).

Figure 77-13 Aggregate of sludge on ultrasound. **A.** Sagittal ultrasound image of the gallbladder demonstrates an echogenic nonshadowing abnormality located dependently within the gallbladder lumen (arrow). **B.** When the patient is imaged in the upright position, this abnormality changes location and configuration (arrow), confirming aggregate of sludge rather than soft tissue mass.

Cholescintigraphy

The hepatic parenchyma is normally observed within 1 minute, with peak activity at 10 to 15 minutes.³⁸ The bile ducts are usually visible within 10 minutes, and the gallbladder should appear within 1 hour if the cystic duct is patent (Fig. 77-14A). If the gallbladder has not been defined, imaging should be carried out farther, up to 4 hours. Prompt biliary excretion of tracer without demonstration of the gallbladder is the hallmark of acute cholecystitis (Fig. 77-14B). As noted before, false-positive results may occur in patients with abnormal bile flow because of liver disease or a prolonged fast with distended sludge-filled gallbladder. Also, delayed gallbladder filling can occur in the setting of chronic cholecystitis. If the gallbladder is not visualized after 1 hour and there is visualization of the biliary tree and duodenum, intravenous morphine may be administered, which causes spasm of the sphincter of Oddi,

raising pressure within the bile ducts and increasing the likelihood of bile flow into the gallbladder. If the patient has been fasting for more than 24 hours, an oral fatty meal or intravenous cholecystokinin may be administered, resulting in gallbladder contraction so that the gallbladder can empty and then refill.

Ultrasound

The ultrasound findings in acute uncomplicated cholecystitis are well described and include gallstones, sonographic Murphy sign, gallbladder distention, wall thickening, and pericholecystic fluid^{26,27,39-41} (Figs. 77-15 and 77-16). The sonographic Murphy sign refers to maximum tenderness during compression with the ultrasound transducer placed directly over the gallbladder. Of these findings, the first two are considered the most specific. In a study by Ralls and coworkers,⁴² the sonographic Murphy sign and the presence of gallstones had a positive predictive value of 92% for the diagnosis of acute cholecystitis. It is cautioned that the sonographic Murphy sign may be blunted if the patient has received pain medication before ultrasound evaluation. Furthermore, impaired mental status may preclude evaluation of this sign. Last, the sonographic Murphy sign may be absent in the setting of gangrenous cholecystitis (see later). If it can be demonstrated that a stone is impacted in the gallbladder neck or cystic duct, this is also an important finding that increases the likelihood of acute cholecystitis (Fig. 77-15B). To determine that a stone is impacted in the gallbladder neck or cystic duct requires evaluating the patient in the left lateral decubitus or upright position to assess for mobility of the stone.

Less specific ultrasound findings of acute cholecystitis include gallbladder distention, wall thickening, pericholecystic fluid, and the presence of other intraluminal material such as sludge. In most cases of acute cholecystitis, the gallbladder will be distended. An exception to this occurs when acute cholecystitis complicates chronic cholecystitis, when there may be mural fibrosis impeding distention. Also, if there has been free perforation of the gallbladder, it may appear completely collapsed (discussed further later). Diffuse gallbladder wall thickening, measuring more than 3 mm, is present in 50% to 75% of patients with acute cholecystitis but may also be associated with chronic inflammation.²⁶ Furthermore, gallbladder wall thickening may be associated with many other conditions, including liver disease such as acute hepatitis (Fig. 77-17), ascites, hypoalbuminemia, and alcoholism as well as congestive heart failure, acquired immunodeficiency syndrome (AIDS), and sepsis. In patients with AIDS, cholangiopathy may be related to infection with organisms such as *Cryptosporidium*. Other causes include adenomyomatosis and gallbladder neoplasm. In acute cholecystitis, wall thickening is generally diffuse; if it is more focal, a complication such as gangrenous change or another cause, such as neoplasm, should be considered. Pericholecystic fluid is generally associated with more severe cholecystitis and may be associated with perforation or abscess formation. However, this may also be nonspecific, especially in the setting of generalized ascites. Other entities that clinically can mimic acute cholecystitis, such as peptic ulcer disease and pancreatitis, may also be associated with pericholecystic fluid. Sludge, related to bile stasis, can develop in patients with acute cholecystitis due to gallbladder obstruction.

The role of color and power Doppler evaluation as an adjunct to gray-scale imaging in the diagnosis of acute cholecystitis is somewhat controversial. Although there may be overlap between findings in acute and chronic cholecystitis,⁴³ there may be a

Figure 77-14 Cholescintigraphy. **A.** Negative hydroxy iminodiacetic acid (HIDA) scintiscan shows prompt filling of the gallbladder lumen with tracer, confirming patency of the cystic duct. **B.** Positive HIDA scan. There is no filling of the gallbladder, confirming obstruction of the cystic duct and the presence of acute cholecystitis. (Images courtesy Dr. Elissa Kramer, Department of Nuclear Medicine, New York University Medical Center.)

Figure 77-15 Acute cholecystitis: ultrasound. **A.** Gallbladder (g) is distended, with mural thickening (arrowhead) and a stone in the gallbladder neck (arrow). Sonographic Murphy sign was present. **B.** In the upright position, the gallbladder (g) is distended, and pericholecystic fluid is evident (arrowhead). Stone (arrow) does not change location, confirming impaction in gallbladder neck.

Figure 77-16 Acute cholecystitis: ultrasound. **A.** Sagittal scan demonstrates gallbladder distention (g) and wall thickening (calipers). Arrow, Stones in gallbladder neck. **B.** Transverse scan of gallbladder (g) demonstrates wall thickening (arrowhead) and pericholecystic fluid (arrow). A sonographic Murphy sign was demonstrated.

Figure 77-17 Gallbladder manifestations of acute hepatitis: ultrasound findings. Sagittal (**A**) and transverse (**B**) images of the gallbladder demonstrate that the gallbladder lumen (g) is not significantly distended. The wall is markedly thickened (arrows) and has a striated appearance, indicating mural edema.

potential role for Doppler evaluation of the inflamed gallbladder⁴⁴ (Fig. 77-18).

Computed Tomography

Although it is not the first-line imaging modality for the evaluation of suspected acute gallbladder disease, the role of CT in the evaluation of the patient with acute abdominal pain continues to expand. The cause of the patient's symptoms may initially be unclear because of nonspecific clinical findings. In this setting, CT may be the initial study performed as it allows more comprehensive evaluation of the abdomen and pelvis and can identify other acute inflammatory processes that may simulate acute cholecystitis. Therefore, it is important to become familiar with the spectrum of CT findings in acute cholecystitis. CT is also a useful adjunct to ultrasound when ultrasound findings are equivocal or when a complicated form of cholecystitis is suspected⁴⁵ (see later). In a retrospective study at the author's institution,⁴⁶ the overall sensitivity, specificity, and accuracy of CT for the diagnosis of acute cholecystitis were 91.7%, 99.1%, and 94.3%, respectively.

The CT findings of acute cholecystitis include gallstones, gallbladder distention, thickening of the gallbladder wall, pericholecystic inflammation, and fluid^{17,41,47-50} (Fig. 77-19). The CT findings of acute cholecystitis have been divided into major and minor criteria.⁵¹ Major findings include calculi, mural thickening of the gallbladder, pericholecystic fluid, and subserosal edema. Minor findings are gallbladder distention and sludge. CT is limited with respect to detection of gallstones as only up to 75% are visualized.¹⁷ Of these signs, the presence of pericholecystic inflammatory change is believed to be the most

specific.^{17,48} Gallbladder wall thickening on CT is a nonspecific finding and may be secondary to a broad spectrum of both inflammatory and neoplastic disorders.⁵² Gallbladder carcinoma tends to cause greater mural thickening than benign disorders do.⁵³

On occasion, it may be difficult to differentiate gallbladder wall thickening from pericholecystic fluid. Pericholecystic fluid tends to be more focal and irregularly margined, whereas mural thickening is concentric. Punctate foci of contrast enhancement corresponding to enhancing vessels within the gallbladder wall may be observed. A target appearance corresponds to an inner layer of enhancing mucosa and an outer layer of enhancing serosa with hypoattenuating submucosal edema between the two.

An ancillary CT finding of gallbladder inflammation is increased contrast enhancement in the liver parenchyma adjacent to the gallbladder^{50,54,55} (Fig. 77-20). This finding results from hepatic arterial hyperemia secondary to gallbladder inflammation. Increased density of the gallbladder wall has been described as a finding on unenhanced CT, found in approximately 51% of patients.⁵⁶ This is found in patients with mucosal hemorrhage and necrosis and may be a predictor of gangrenous change.

A study evaluating the use of 64-section helical CT for quantitative and qualitative assessment of acute cholecystitis found that pericholecystic fat stranding, mural stratification, pericholecystic hypervascularity, spontaneous hyperattenuation of the gallbladder wall, short (≥ 32 mm) and long (≥ 74 mm) gallbladder axis enlargement, and gallbladder wall thickening (≥ 3.6 mm) were the most discriminating and independent variables for the

Figure 77-18 Acute cholecystitis: Doppler ultrasound. **A.** Sagittal scan of the gallbladder (g) demonstrates distention and wall thickening. Increased mural vascularity is demonstrated (arrow) with power Doppler. **B.** Spectral Doppler tracing confirms arterial waveform.

There is focal increase in contrast enhancement of the liver parenchyma adjacent to the gallbladder (arrow), representing hyperemia related to adjacent gallbladder inflammation.

CT diagnosis of acute cholecystitis.⁵⁷ Comparative studies assessing accuracy of CT versus ultrasound for diagnosis of acute cholecystitis are limited. In a study by van Randen and associates⁵⁸ that compared CT and ultrasound in 52 patients with acute cholecystitis, diagnostic accuracy did not differ significantly between the two modalities. However, in their meta-analysis, Kiewiet and colleagues³⁷ cautioned that additional studies evaluating the diagnostic accuracy of CT for acute cholecystitis are needed and that there is currently not enough evidence to support indiscriminate use of this modality in patients suspected of having acute cholecystitis.

Brook and associates⁵⁹ reviewed 14 cases of misdiagnosis of acute cholecystitis at both ultrasound and CT in their practice during a 5-year period. Eight cases of misdiagnosis involved ultrasound and six cases involved CT. Three cases of overcall on ultrasound included cases of gallbladder wall edema that ultimately were diagnosed as hepatitis, sepsis, and chronic cholecystitis. In none of these patients was the gallbladder distended. Therefore, if the gallbladder wall is thickened but there is no distention, an alternative diagnosis should be considered. Two cases of undercall at ultrasound were in patients in the intensive care unit, and two cases were due to lack of wall edema. In an additional patient, diagnosis was delayed because the ultrasound report was not definitive. All of the misdiagnoses at CT were due to undercalls; in one patient, lack of intra-abdominal fat hindered recognition of pericholecystic fat stranding. In another patient, pericholecystic increased arterial enhancement in the liver was mistaken for fatty sparing, and in an additional patient, wall edema and mucosal enhancement were mistaken for a calculus.

Magnetic Resonance Imaging

Like CT, MRI is usually used in the setting of suspected acute cholecystitis when other imaging findings are equivocal or the clinical setting is ambiguous.⁶⁰⁻⁶⁴ Magnetic resonance cholangiopancreatography (MRCP) is sensitive in the diagnosis of

choledocholithiasis, which is particularly important if laparoscopic cholecystectomy is performed. In addition to gallstones, MR readily demonstrates gallbladder wall edema, which is manifested as high signal intensity on T2-weighted images.^{62,65} In one series, pericholecystic high signal intensity on single-shot fast spin-echo (SSFSE) images had an overall accuracy of 89%, specificity of 79%, positive predictive value of 87%, and negative predictive value of 85% for the diagnosis of acute cholecystitis.⁶⁶ Loud and associates⁶¹ found contrast-enhanced T1-weighted images useful for the diagnosis of acute cholecystitis. Patients with surgically proved acute cholecystitis had greater than 80% contrast enhancement of the wall, which helped differentiate acute from chronic cholecystitis. A transient increase in hepatic enhancement may be seen around the gallbladder in 70% of cases during the arterial phase of enhancement and, as with CT, may be an important indicator of acute gallbladder inflammation^{61,62} (Fig. 77-21). Altun and colleagues⁶⁷ found that increased gallbladder wall enhancement and increased transient pericholecystic hepatic enhancement had the highest combination of sensitivity and specificity for the diagnosis and differentiation of acute and chronic cholecystitis. MR has been shown to be superior to ultrasound for detection of obstructing calculi in the gallbladder neck and the cystic duct (Fig. 77-21C, D).⁶⁸ MRI may also be helpful to identify complications of acute cholecystitis. In the meta-analysis by Kiewiet and colleagues,³⁷ diagnostic accuracy of MR for diagnosis of acute cholecystitis was found to be comparable to that of ultrasound, and it is suggested as a helpful imaging modality when ultrasound is technically limited. MRCP is more completely discussed in Chapter 75.

Acute Acalculous Cholecystitis

PATHOGENESIS AND EPIDEMIOLOGY

The reported incidence of acute cholecystitis in the absence of gallstones ranges from approximately 5% to 10%.²⁶ In one large surgical series,⁶⁹ acute acalculous cholecystitis (AAC) represented 14% of cases of acute cholecystitis and was responsible for 2% of all cholecystectomies. Bile stasis, gallbladder ischemia, cystic duct obstruction, and systemic infection are considered to be the most important factors in pathogenesis of AAC.^{70,71} Histologic features include gallbladder wall inflammation, with necrosis of blood vessels in the muscularis and serosa of the gallbladder.⁷² AAC occurs with increased incidence in patients who are critically ill or with prolonged illness, such as in the setting of trauma or after prolonged stay in the intensive care unit. Other risk factors include major cardiovascular disorders, cardiopulmonary bypass, diabetes, autoimmune disease, bacterial and fungal sepsis, hyperalimentation, and AIDS. Although it is much less common, the disease can occur *de novo* in the absence of these other risk factors in otherwise apparently healthy individuals.^{73,74}

AAC is a more fulminant form of acute cholecystitis with higher morbidity and mortality and rapid progression to gangrene and perforation. Mortality is reported to be as high as 65%⁷⁵; therefore, early diagnosis is important. The diagnosis of AAC, however, often presents a challenge, particularly if there are no apparent risk factors. Clinical findings, such as fever and leukocytosis, are nonspecific. The diagnosis should be suspected in critically ill or injured patients who have fever or infection with no other apparent source.

IMAGING

Ultrasound

The reported sensitivity of ultrasound in AAC varies widely from 36% to 92%⁶⁹ (Fig. 77-22). Gallstones are not present, and afflicted patients are often insensitive to pain because of altered mental status or medications, thus making the sonographic

Murphy sign unreliable.⁷⁶ These patients may also have hypoalbuminemia, congestive heart failure, and long-standing parenteral nutrition, all of which are associated with gallbladder wall thickening, distention, and sludge. There is a great degree of overlap in ultrasound findings of intensive care unit patients with AAC and those without. In one study evaluating the ultrasound findings in intensive care unit patients, the majority of

Figure 77-21 Acute cholecystitis: MR findings.
A. T2-weighted HASTE image demonstrates gallbladder distention (g). Dependent low signal gallstones are evident. Gallbladder wall is thickened, and there is pericholecystic fluid (arrow). **B.** Contrast-enhanced T1-weighted gradient-echo fat-suppressed image demonstrates gallbladder distention (g) with wall thickening. Increased enhancement is present in adjacent liver parenchyma (arrow). **C.** Coronal HASTE image demonstrates distended gallbladder with multiple stones. Arrowhead, Stone in gallbladder neck. **D.** Coronal HASTE image demonstrates normal common bile duct (arrow).

Figure 77-22 Acute acalculous cholecystitis: ultrasound and CT findings.
A. Gallbladder (g) is distended, with mural thickening (arrow), and contains dependent echoes indicating sludge (arrowhead). These are common ultrasound findings in acutely ill patients. **B.** Noncontrast CT scan demonstrates gallbladder distention (g) with inflammatory changes in pericholecystic fat (arrow), confirming presence of gallbladder inflammation.

patients had some abnormality of the gallbladder.⁷⁷ Nevertheless, ultrasound has the advantage of being performed portably at the bedside and remains a reasonable first study for the diagnosis of AAC. Despite limitations, the American College of Radiology appropriateness criteria assign ultrasound the highest ranking for diagnosis of AAC.²⁸

Cholescintigraphy is also of limited value in the diagnosis of AAC, with a significant false-positive rate (nonvisualization of the gallbladder) of up to 40% in patients with hepatocellular dysfunction, prolonged fasting, or severe illness.^{76,78} A negative study is useful for excluding acalculous cholecystitis; however, a positive study must be interpreted with caution. The specificity can be improved to 88% with the use of morphine.⁷⁹ A prospective study comparing ultrasound and morphine scintigraphy in the diagnosis of AAC found the sensitivity of ultrasound and morphine scintigraphy to be 50% and 67%, specificity 94% and 100%, positive predictive value 86% and 100%, negative predictive value 71% and 80%, and accuracy 75% and 86%, respectively.⁸⁰ Combining the two modalities may lead to greater diagnostic accuracy.

Computed Tomography and Magnetic Resonance Imaging

CT or MRI may be helpful in the diagnosis of AAC in the patient who is stable enough to undergo imaging but should generally be performed as an adjunct to ultrasound. With the exception of the absence of gallstones, the CT and MRI findings of AAC are similar to those of calculous cholecystitis. The advantage of these modalities is that they may demonstrate pericholecystic inflammatory change and fluid and abnormalities of the gallbladder wall or adjacent hepatic parenchyma that may not be appreciated at sonography, allowing a more specific diagnosis^{60,62,81-83} (Fig. 77-23). However, as at sonography, less specific findings that may be observed include gallbladder distention, sludge, and wall thickening. A study demonstrated,

however, that a totally normal gallbladder at CT excluded the diagnosis of AAC.⁸⁴

Many times, these patients are too ill for additional cross-sectional imaging evaluation. If no other source of sepsis is discovered, it may be prudent to proceed with percutaneous cholecystostomy, which can be performed at the bedside. This has been shown to be a safe and effective procedure in the patient with acute cholecystitis who is not a surgical candidate.⁸⁵ This can be helpful, for both diagnosis and treatment, in patients with sepsis of unknown cause and equivocal imaging findings of AAC.^{86,87} A study showed that percutaneous cholecystostomy was superior to gallbladder aspiration in terms of clinical effectiveness and was associated with the same complications.⁸⁸

Complications of Acute Cholecystitis

GANGRENOUS CHOLECYSTITIS

Gangrenous cholecystitis is a severe form of acute cholecystitis associated with vascular compromise and intramural hemorrhage, necrosis, and intramural abscess formation. This is usually caused by a stone impacting the cystic duct, with progressive distention of the gallbladder and ultimately ischemic necrosis of the wall.⁸⁹ The incidence ranges from 2% to approximately 30% in various surgical series.⁹⁰⁻⁹² The incidence is increased in men, patients of advanced age, and those with cardiovascular disease. Once it is diagnosed, treatment is generally emergency cholecystectomy to avoid life-threatening complications, such as perforation. There is a higher rate of conversion to open cholecystectomy than in uncomplicated acute cholecystitis.⁹³⁻⁹⁵

At sonography, the features of gangrenous cholecystitis include heterogeneous, striated thickening and irregularity of the gallbladder wall and intraluminal membranes resulting from desquamation of the gallbladder mucosa^{96,97} (Figs. 77-24

Figure 77-23 Acute acalculous cholecystitis: ultrasound and MR features. **A.** Ultrasound demonstrates markedly distended gallbladder (g) with layering sludge (arrow). **B.** Axial T1-weighted fat-suppressed gradient-echo image with gadolinium enhancement demonstrates distended gallbladder (g), wall thickening, and pericholecystic inflammatory change. Arrow points to small intramural abscess not suspected clinically.

and 77-25). The irregular or asymmetric thickening of the gallbladder wall probably results from ulceration, hemorrhage, necrosis, or microabscess formation. In a series by Jeffrey and colleagues,⁹⁷ these findings were present in 50% of patients. A striated appearance of the gallbladder wall was found in 40% of patients in the series by Teefey and associates.⁹⁶ However, in a more recent analysis by this author, this finding was nonspecific for the presence of gangrenous cholecystitis and found in nongangrenous cholecystitis and other conditions that cause gallbladder wall edema, such as hepatitis.⁹⁸ The presence of

intraluminal membranes is considered a more specific finding (see Fig. 77-25). The sonographic Murphy sign may not be present because of associated denervation of the gallbladder wall. In a series by Simeone and colleagues,⁹⁹ the sonographic Murphy sign was present in only 33% of patients with gangrenous cholecystitis. Additional findings include intramural abscess formation and pericholecystic fluid collection or abscess formation caused by perforation of the gallbladder.

CT findings of gangrenous cholecystitis parallel findings at sonography and include intraluminal membranes, intraluminal

Figure 77-24 Acute gangrenous cholecystitis: ultrasound findings. Sagittal (A) and transverse (B) ultrasound images demonstrate distended gallbladder (g) containing intraluminal sludge (s). Gallbladder wall is irregular in contour with asymmetric thickening (arrow). C. Laparoscopic cholecystectomy image shows edematous, ischemic gallbladder wall.

Figure 77-25 Acute gangrenous cholecystitis: ultrasound features. A. Sagittal image demonstrates echogenic, nonshadowing intraluminal material indicating aggregates of sludge (black arrow). Curvilinear intraluminal echogenic regions (white arrows) represent intraluminal membranes secondary to sloughed mucosa. B. Transverse image demonstrates intraluminal membranes (arrows) in gallbladder (g) lumen.

hemorrhage, irregularity or disruption of the gallbladder wall, and pericholecystic abscess^{17,46,48,100-102} (Fig. 77-26). An additional finding detectable at CT is irregular or lack of gallbladder wall enhancement^{46,102} (Fig. 77-27). A study by the author evaluated the sensitivity and specificity of CT for the diagnosis of gangrenous cholecystitis.⁴⁶ CT was highly specific for identifying acute gangrenous cholecystitis (96%) but had low sensitivity (29.3%). The most specific findings at CT for the presence of gangrenous cholecystitis were gas in the gallbladder wall or lumen, intraluminal membranes, irregularity or absence of the gallbladder wall, pericholecystic abscess, and lack of gallbladder wall enhancement. In this study, the presence of pericholecystic fluid, degree of gallbladder distention in the short axis, and degree of mural thickening were also predictive of the severity of gallbladder inflammation. In a more recent study by Wu and associates,¹⁰³ the presence of a perfusional defect of the gallbladder wall (discontinuity or decreased enhancement of the gallbladder wall) was associated with CT diagnosis of gangrenous cholecystitis with accuracy of 80%, sensitivity of 70.6%, specificity of 100%, and positive predictive value of 100%. Therefore, when CT is performed to evaluate for cholecystitis, contrast material should be administered intravenously if possible because this improves delineation of the wall and identification of lack of enhancement, intramural abscess, and focal disruption, which are important features of gangrenous cholecystitis.

Gallbladder carcinoma may be mimicked by the mural changes in acute cholecystitis, particularly gangrenous cholecystitis, and this is an important potential pitfall. If there is concern on the basis of ultrasound findings, CT may be of benefit in demonstrating an enhancing gallbladder mass and

detecting direct invasion of the liver and presence of liver metastases.⁴⁵ Liang and colleagues¹⁰⁴ found that in the differentiation of acute cholecystitis and gallbladder carcinoma, features that favored carcinoma included focal gallbladder wall thickening, intraluminal mass, nondistended gallbladder with diffuse wall thickening, and enlarged regional lymph nodes.

HEMORRHAGIC CHOLECYSTITIS

Hemorrhagic cholecystitis is an uncommon complication of acute cholecystitis and usually occurs in the setting of cholelithiasis and gangrenous cholecystitis. Transmural inflammation causes mural necrosis and ulceration and results in hemorrhage into the gallbladder lumen.¹⁰⁵⁻¹⁰⁷ Atherosclerotic change in the gallbladder wall may be a predisposing factor.¹⁰⁷ Blood clots in the lumen may become impacted in the cystic duct or common bile duct (CBD) or pass into the small bowel. The clinical presentation may be identical to uncomplicated acute cholecystitis with fever and right upper quadrant pain but may also include biliary colic, jaundice, hematemesis, and melena.¹⁰⁸ Massive upper gastrointestinal bleeding and hemoperitoneum rarely occur.¹⁰⁹ Prompt diagnosis is essential because of the associated high mortality rate.

At sonography, blood in the gallbladder lumen can be recognized as hyperechoic material that demonstrates greater echogenicity than sludge (Fig. 77-28). This may form a dependent layer; however, clotted blood may appear as a clump or mass adherent to the gallbladder wall or heterogeneous echogenic material.^{105,108,110} An organized clot may simulate a polypoid, intraluminal mass.¹¹¹ As the hemorrhage evolves, the clot may become more cystic in appearance.¹¹² In addition to

Figure 77-26 Acute gangrenous cholecystitis: CT findings. **A** and **B.** Gallbladder (g) is distended with thickened, irregularly enhancing wall. Arrow, Intraluminal membranes. **C.** Scan obtained in a different patient shows distended gallbladder (g) with thickened wall, which demonstrates heterogeneous contrast enhancement. Low-attenuation areas correspond to intramural abscesses (a). Arrow, Loculated pericholecystic fluid collection secondary to contained gallbladder perforation. **D.** Slightly more inferior image demonstrates intraluminal membranes (arrows).

Figure 77-27 CT of gangrenous cholecystitis: lack of mural contrast enhancement. **A.** There is apparent discontinuity of the gallbladder wall (arrows) where no mucosal enhancement is noted. *g*, Distended gallbladder. **B.** Contrast-enhanced CT scan in a second patient demonstrates distended gallbladder (*g*) with extensive pericholecystic inflammatory change. There is no contrast enhancement of gallbladder wall.

other findings of cholecystitis, CT shows increased density of bile¹⁰⁵ (see Fig. 77-28B). A fluid-fluid level may be observed with a high-attenuation dependent component simulating the hematocrit effect observed in acute hemorrhage¹⁰⁸ (Fig. 77-29A). Other causes of high-density bile include biliary excretion of iodinated contrast material and milk of calcium; these do not generally appear as echogenic at sonography, nor is a fluid-fluid level observed. If there is associated perforation of the gallbladder, hemoperitoneum will also be observed (Fig. 77-29B). If there is active bleeding at the time of contrast-enhanced CT, this may appear as active extravasation of intravenous contrast material inside the gallbladder lumen.¹¹³ On MRI, blood products appear as high signal intensity within the gallbladder lumen on T1-weighted images and moderate to high heterogeneous signal intensity on T2-weighted images.⁶²

Figure 77-28 Hemorrhagic cholecystitis: ultrasound and CT findings. **A.** Sagittal ultrasound scan demonstrates distended gallbladder (*g*) with lumen completely filled with echogenic material corresponding to hemorrhagic bile. **B.** CT scan demonstrates distended gallbladder (*g*) with fluid-fluid level (arrow) with high-attenuation dependent component. These findings represent intraluminal blood clot.

The multiplanar capability of MRI may help differentiate intraluminal blood from hemorrhage in the wall. MR angiography may supplement conventional imaging if vascular disease is suspected.

EMPHYSEMATOUS CHOLECYSTITIS

Emphysematous cholecystitis is a rare life-threatening and rapidly progressive complication of acute cholecystitis. Cystic artery compromise is thought to promote the proliferation of gas-producing organisms in an anaerobic environment and penetration of gas into the gallbladder wall.^{114,115} The organisms most commonly isolated are *Clostridium welchii* and *Escherichia coli*.¹¹⁵ At pathologic examination, gallbladders with emphysematous cholecystitis have a higher incidence of endarteritis obliterans, supporting vascular insufficiency as a causative factor. This complication occurs with higher frequency in

patients with diabetes (up to 50%) and male patients (up to 71%).¹¹⁶ Gallstones may be absent in up to one third of patients, and there is a high risk of gangrene and a perforation rate five times higher than in acute uncomplicated cholecystitis.^{116,117}

The mortality rate for emphysematous cholecystitis is 15% versus 4% in uncomplicated acute cholecystitis.¹¹⁶ Therefore, prompt diagnosis is critical. The clinical presentation is often indistinguishable from uncomplicated acute cholecystitis. In the diabetic patient, in particular, severe symptoms may be absent, and there needs to be a high clinical index of suspicion. Before cross-sectional imaging, emphysematous cholecystitis

was diagnosed on the abdominal radiograph and classically described in three stages: stage 1, gas in the gallbladder lumen; stage 2, gas in the gallbladder wall; and stage 3, gas in the pericholecystic soft tissues. Ultrasound and CT are now considered more sensitive in the detection of smaller amounts of gas.

Ultrasound findings vary by the amount and location of gas.^{26,27,118,119} A small amount of gas in the wall may appear as an echogenic focus with associated ring-down or comet-tail artifact. Larger amounts of gas and intraluminal gas may appear as a curvilinear arc of increased echogenicity with associated “dirty” posterior acoustic shadowing²⁶ (Fig. 77-30A). In this setting, the

Figure 77-29 Hemorrhagic cholecystitis: CT findings. **A.** CT demonstrates distended gallbladder containing layering material of high attenuation corresponding to intraluminal blood (white arrow). There has been perforation of the gallbladder, resulting in hemoperitoneum (black arrow). **B.** Additional blood is demonstrated in the pelvis (arrow).

Figure 77-30 Emphysematous cholecystitis: ultrasound and CT features. **A.** Sagittal gallbladder (g) scan demonstrates an arc of increased echogenicity (arrow) in expected location of the gallbladder wall. This is associated with “dirty” posterior acoustic shadowing (arrowhead), suggesting intramural gas. **B.** Transverse image demonstrates intramural gas (arrow) and intraluminal echogenic foci with posterior acoustic shadowing (arrowhead), indicating gallstones. **C.** Noncontrast CT demonstrates gas (white arrows) within lumen and wall of gallbladder (g). Low-attenuation area in the adjacent liver is due to an abscess (black arrow). **D.** Gas (arrows) is present in the pericholecystic soft tissues.

gallbladder may be difficult to visualize owing to associated acoustic shadowing. On sonographic evaluation, it may be difficult to differentiate emphysematous cholecystitis from a contracted gallbladder with stones or a porcelain gallbladder with calcified wall.¹¹⁸

CT has a higher sensitivity than sonography for the identification of emphysematous cholecystitis and plays an important complementary role to ultrasound.¹²⁰ If emphysematous cholecystitis is suspected at sonography or there is a high clinical index of suspicion and ultrasound findings are equivocal, CT should be performed. CT is also indicated when the gallbladder cannot be adequately visualized at sonography. CT findings include gas within the gallbladder wall or nondependent portion of the lumen^{45,121,122} (Fig. 77-31). There may be extension into the pericholecystic soft tissues. CT may also demonstrate other complications, such as abscess formation and perforation (Fig. 77-30C, D and Fig. 77-31B, C). Free intraperitoneal gas indicates associated free gallbladder perforation and constitutes a surgical emergency.

The MRI features of emphysematous cholecystitis have not yet been well described. A report describing MRI features in a case of emphysematous cholecystitis included (1) a signal void in the nondependent portion of the gallbladder and intermediate signal intensity fluid in the dependent portion of the gallbladder, representing a gas-fluid level; (2) a low signal intensity rim surrounding the gallbladder, indicating gas in the gallbladder wall; and (3) regions of very low signal intensity in the pericholecystic soft tissues, indicating extraluminal gas due to

perforation.¹²³ Gas can be recognized as blooming artifact on gradient-echo and echo planar sequences.

GALLBLADDER PERFORATION

Gallbladder perforation can occur in the setting of cholelithiasis, cholecystitis, trauma, neoplasm, steroid use, or vascular compromise. Perforation is most often a complication of severe acute cholecystitis, occurring in approximately 8% to 12% of cases.^{124,125} In one series, associated mortality was 24.1%.¹²⁴ In acute cholecystitis, progressive gallbladder distention and inflammation is followed by vascular compromise, gangrene, necrosis, and ultimately perforation.^{125,126} The fundus is the most frequent site of perforation because of the relatively poor blood supply in this area. Associated complications include bacteremia, septic shock, bile peritonitis, and abscess formation, with mortality rates ranging from 6% to 70%.^{124,127-130}

Gallbladder perforation has been classified into three types¹²⁷: (1) acute free perforation into the peritoneal cavity, (2) subacute perforation with pericholecystic abscess, and (3) chronic perforation with cholecystenteric fistula formation. Subacute perforation with pericholecystic abscess formation is the most common type.¹²⁸ Abscess formation may be confined to the gallbladder fossa or spread into the peritoneal cavity or involve the liver.^{131,132} Type 1 free perforation is associated with the highest mortality rate.¹²⁸ Type 3 perforation is associated with gallstone ileus, discussed later in this chapter.

Figure 77-31 Emphysematous cholecystitis: ultrasound and CT features.

A. Sagittal ultrasound demonstrates distended gallbladder (g) with thickened wall (arrowhead). Anterior wall (arrow) demonstrates increased echogenicity with dirty posterior acoustic shadowing, consistent with gas. **B.** Noncontrast CT demonstrates crescent of gas (white arrow) in gallbladder (g) wall. Extraluminal gas (black arrow) indicates perforation. **C.** Coronal reformatted CT image demonstrates gas in a dependent location (white arrow), confirming intramural location. Gas in pericholecystic soft tissues (black arrow) indicates perforation. g, Gallbladder.

Prompt diagnosis of gallbladder perforation is imperative. Emergent cholecystectomy is the treatment of choice. Clinical signs and symptoms may be nonspecific and may be indistinguishable from uncomplicated cholecystitis, particularly in the diabetic patient, so that imaging plays an important diagnostic role.¹³³ At sonography, the gallbladder wall is irregular or ill-defined with focal or global loss of its normal sonorefectivity.⁴⁵ There is a large amount of pericholecystic fluid or a loculated pericholecystic collection¹²⁶ (Fig. 77-32A). A focal defect in the wall of the gallbladder is a more specific finding but may not always be visualized¹³⁴ (Fig. 77-33A, B).

CT plays an important role in the evaluation of suspected gallbladder perforation when ultrasound findings are equivocal.^{131,135,136} Interruption of the gallbladder wall or a focal mural defect may be more readily identified at CT (Fig. 77-33C). Associated findings include pericholecystic or intrahepatic abscess and spilled stones (see Fig. 77-32B). Free gallbladder perforation is identified when there is free intraperitoneal fluid corresponding to bile (Fig. 77-34). In this setting, the gallbladder may be collapsed, which may provide an additional diagnostic challenge as the diagnosis of acute cholecystitis may not be readily apparent. In these instances, presence of localized pericholecystic inflammatory change offers a diagnostic

Figure 77-32 Gallbladder perforation. **A.** Ultrasound demonstrates complex fluid collection in gallbladder fossa (arrow). Gallbladder wall is not delineated, and perforated gallbladder with abscess was suspected. Arrowhead, Gallstones. **B.** Noncontrast CT image demonstrates a large complex fluid collection in gallbladder fossa (arrow). There are spilled gallstones (arrowheads) due to gallbladder perforation.

Figure 77-33 Gallbladder perforation. **A.** Sagittal scan shows mural thickening with striations (arrowhead). Arrow, Multiple gallstones. **B.** Sagittal scan obtained with a linear transducer (8 MHz) produces higher resolution image. Focal defect in gallbladder wall (black arrow) is now evident. This indicates a focal intramural abscess or contained perforation. White arrows, Gallstones. **C.** Contrast-enhanced CT confirms focal defect (arrow) in gallbladder (g) wall. Mural thickening and pericholecystic inflammatory changes are present, consistent with acute cholecystitis.

Figure 77-34 Free perforation of the gallbladder with associated bile peritonitis.

Patient presented with several days of right upper quadrant pain and fever. **A.** Contrast-enhanced CT demonstrates that the gallbladder (g) is not distended. Calcified stone (black arrow) appears to be outside of gallbladder lumen. White arrow, Perihepatic free fluid. **B.** Image of the pelvis demonstrates moderate free fluid (f) corresponding to bile.

clue as to the etiology of free fluid and peritoneal inflammatory changes.

In a study comparing ultrasound with CT in 13 patients with surgically proven gallbladder perforation, a mural defect was visualized in 7 patients (53.8%) at CT but in no patient on ultrasound.¹³⁶ Ultrasound and CT were similar in demonstrating pericholecystic fluid collections, gallbladder wall thickening, and cholelithiasis. Bulging or irregular contour of the gallbladder was demonstrated on ultrasound in five cases and on CT in two cases. In all cases, the site of the gallbladder wall defect or bulging on ultrasound or CT corresponded to the site of perforation. These authors concluded that CT was superior to ultrasound for the diagnosis of gallbladder perforation because of improved ability to demonstrate a focal wall defect. A more recent study by Sood and associates,¹³⁷ however, found that there was no statistically significant difference in the ability of ultrasound or CT to detect a focal wall defect in 18 patients evaluated with both modalities. This may be due to recent improvements in ultrasound technology, allowing better resolution and definition of the gallbladder wall. MR, because of its superior soft tissue resolution and multiplanar imaging capability, may also be a useful adjunct if ultrasound and CT findings remain equivocal.

Chronic Cholecystitis

PATHOGENESIS AND EPIDEMIOLOGY

Chronic cholecystitis is associated with cholelithiasis in 95% of cases and may occur after a single bout or multiple recurrent episodes of acute cholecystitis. Etiology is related to intermittent obstruction of the cystic duct or neck as well as gallbladder dysmotility.² Chronic inflammatory changes cause the gallbladder wall to become thickened and fibrotic, and with increasing fibrosis, the gallbladder eventually becomes shrunk and distorted. If there are coexisting acute and chronic inflammatory changes at pathologic examination, the term *chronic active cholecystitis* may be used.¹³⁸

IMAGING

A diagnosis of chronic cholecystitis is difficult to establish with imaging, and clinical correlation is required. Ultrasound findings include gallstones and thickened gallbladder wall with contraction of the gallbladder that persists in the

fasting state (Fig. 77-35). On CT, pericholecystic inflammatory change may be absent.⁵⁰ On MR, gallbladder wall thickening related to chronic inflammation will demonstrate low signal intensity, whereas acute cholecystitis is associated with edema in the wall, which demonstrates increased signal intensity on T2-weighted images.⁶² Also, the increased perihepatic contrast enhancement observed with acute cholecystitis can be helpful in differentiating acute from chronic inflammation.^{61,62,67}

CHRONIC ACALCULOUS CHOLECYSTITIS

Chronic acalculous cholecystitis, a disorder characterized by recurrent biliary colic in a patient without radiographic evidence of gallstones, often creates a diagnostic dilemma for clinicians. In the absence of gallstones, it is often difficult to attribute a patient's symptoms to gallbladder inflammation. However, these patients may benefit from cholecystectomy for relief of symptoms.¹³⁹ A specific diagnosis may require nuclear medicine evaluation, including evaluation of the gallbladder ejection fraction. A decrease in gallbladder ejection fraction is a common feature of both calculous and acalculous chronic cholecystitis.¹⁴⁰ Cholecystokinin cholescintigraphy with calculation of gallbladder ejection fraction has been shown to be a predictor of disease as well as of subsequent symptom relief after cholecystectomy.¹⁴¹

XANTHOGRANULOMATOUS CHOLECYSTITIS

Xanthogranulomatous cholecystitis (XGC) is a rare chronic inflammatory condition of the gallbladder, representing a form of chronic cholecystitis. Goodman and Ishak¹⁴² reported the first series of cases at the Armed Forces Institute of Pathology in 1981. The estimated incidence is 1% to 2% of all cases of cholecystitis,¹⁴³ and most patients present in the sixth or seventh decade.¹⁴⁴ In one surgical review, this disorder was found in 1.46% of all cholecystectomy specimens and was associated with gallstones in 85%, with average age at presentation of 52 years.¹⁴⁵ The proposed etiology of this disorder involves chronic gallbladder infection, usually in the setting of cholelithiasis, with mural microabscesses that involve Rokitsansky-Aschoff sinuses. This may result from obstruction of gallbladder outflow, extravasation of bile into the gallbladder wall, and mucosal ulceration. Histiocytes accumulate in the gallbladder wall as a reaction to the extravasated bile,

Figure 77-35 Chronic cholecystitis. **A.** Ultrasound demonstrates contracted gallbladder (arrow) in patient with repeated episodes of right upper quadrant pain. Patient was fasting at time of examination. **B.** The finding was confirmed at CT, with completely contracted gallbladder (arrow). Cholecystectomy was performed, and chronic cholecystitis was confirmed at pathologic examination. **C.** Specimen photograph in a different patient shows multiple stones and a thick gallbladder wall.

and ultimately xanthogranulomatous nodules form in addition to extensive fibrous reaction.¹⁴⁶ On gross examination, the wall is thickened and irregular with yellow or brown nodules of varying sizes. On microscopic examination, the xanthogranulomatous nodules are composed of histiocytes, giant cells, and other chronic inflammatory cells such as lymphocytes and plasma cells. Hemosiderin and extravasated bile along with cholesterol clefts are present in the gallbladder wall. There may be associated biliary obstruction secondary to extrinsic compression of the bile duct and associated Mirizzi syndrome. The gallbladder often becomes adherent to adjacent organs and may be associated with fistula formation. There are no specific clinical or laboratory features, and presentation may be similar to acute or chronic cholecystitis from any cause. Clinical symptoms may include right upper quadrant pain, nausea, vomiting, fever, anorexia, and weight loss.¹⁴⁶

Both the ultrasound and CT features of XGC have been described¹⁴⁶⁻¹⁵¹ and overlap with findings of acute and chronic cholecystitis. On both modalities, the gallbladder wall is often markedly thickened and irregular with loss of normal planes with adjacent structures. An infiltrating mass may be apparent. More recent studies have described the presence of intramural nodules visualized on both sonography and CT (Fig. 77-36). In their series, Chun and colleagues¹⁵⁰ found low-density nodules in 11 cases of XGC, compared with only 7 of 17 cases of carcinoma. Intramural nodules are also a prominent finding of XGC described in other series¹⁴⁷⁻¹⁵¹ as well as a hypoechoic band around the gallbladder.^{147,148} By performing ultrasound on pathologic specimens, Parra and associates¹⁴⁷ showed that the intramural hypoechoic nodules correspond to xanthogranulomatous nodules and the hypoechoic band may correspond to more generalized involvement. However, these nodules may also be confused with intramural abscesses in

gangrenous cholecystitis and large Rokitansky-Aschoff sinuses in adenomyomatosis.

It can be very difficult to prospectively distinguish between XGC and gallbladder carcinoma on cross-sectional imaging studies because of many overlapping features, such as marked gallbladder wall thickening, irregularity, nodularity, and infiltration of the pericholecystic soft tissues. There is a 10% incidence of carcinoma in XGC,¹⁴⁴ and fine-needle aspiration biopsy has been successful in establishing the diagnosis.¹⁵² Surgery is often difficult in these patients, with a high conversion rate to open cholecystectomy. A potential role for diffusion-weighted MRI has recently been proposed, with diffusion restriction seen more frequently in patients with carcinoma and higher apparent diffusion coefficient values in patients with XGC in one series¹⁵³; however, further work in this area is needed.

Choledocholithiasis

PATHOGENESIS AND EPIDEMIOLOGY

Biliary stones that form de novo within the biliary tract are referred to as primary stones, whereas those that migrate from the gallbladder through the cystic duct or a cholecystocholedochal fistula are referred to as secondary stones.¹⁵⁴ The majority of stones within the bile ducts are secondary stones, and pathogenesis is similar to that of gallstones. Migration of gallstones among asymptomatic patients is estimated to occur in 3% to 5% of patients per year, with 1% to 2% of patients per year developing symptoms, including biliary colic or acute pancreatitis.^{155,156} Between 7% and 20% of patients undergoing cholecystectomy are found to have one or more stones in the CBD, and these may be clinically silent.¹⁵⁷ Twenty percent to 30% of patients with gallstone pancreatitis have persistent CBD

Figure 77-36 Xanthogranulomatous cholecystitis. **A.** Ultrasound demonstrates intraluminal echogenic material due to sludge. Gallbladder (g) wall is markedly thickened and contains hypoechoic nodules (arrows). **B.** Contrast-enhanced CT demonstrates marked gallbladder (g) wall thickening and hypoattenuating mural nodes (arrows).

stones that fail to traverse the ampulla.¹⁵⁸ If a stone remains lodged in the CBD, this can also lead to a potentially life-threatening emergency because of associated cholangitis.

Primary stones are classified according to their location within the biliary tract: intrahepatic, extrahepatic, or ampullary. These develop in the setting of bile stasis and colonization of the bile with enteric organisms. Obstruction of bile may be related to inflammatory or iatrogenic strictures, congenital strictures, or perampullary diverticula.¹⁵⁴ These stones are frequently associated with parasitic infections of the biliary tree, such as *Ascaris lumbricoides*. These worms become the nidus for stone and inflammatory stricture formation.

IMAGING

Endoscopic Retrograde Cholangiopancreatography

Endoscopic retrograde cholangiopancreatography (ERCP) and percutaneous transhepatic cholangiography are highly accurate for the detection of choledocholithiasis and also provide access for therapeutic intervention. However, these are invasive procedures with associated risks, including pancreatitis, sepsis, and hemorrhage. The reported complication rate of ERCP ranges from 3.0% to 5.5%, and mortality rate ranges from 0.2% to 1.0%.^{159,160} Therefore, ERCP is generally reserved for patients who require therapy, such as secondary to an impacted stone, or with a high probability of stones and normal findings on prior examinations. Stones within the biliary tract may be readily detected with MRCP but less accurately with ultrasound and CT.

Ultrasound

Ultrasound is the primary imaging modality for evaluation of right upper quadrant pain and is considered superior to CT in the initial imaging evaluation of biliary disease.^{41,161} The reported sensitivity of ultrasound ranges from 22% to 75% for CBD stones.^{3,162-164} Limited sensitivity results in part from inability to completely visualize the duct, particularly distally, because of interposed bowel gas, and distal stones are most commonly overlooked. In a study by Laing and colleagues,¹⁶⁵ 8 of 9 (89%) proximal and 16 of 23 (70%) distal CBD stones were visualized at sonography. Scanning the patient in the erect right posterior oblique or right lateral decubitus position minimizes gas in the gastric antrum and duodenum and improves visualization of the distal duct. Water may also be administered orally

to provide an acoustic window in the gastric antrum or duodenum.²⁷ Improved contrast enhancement and reduction of side lobe artifacts afforded by tissue harmonic imaging improve the sonographic detection of choledocholithiasis.¹⁶⁶ CBD stones appear as echogenic foci, which may or may not cause posterior acoustic shadowing, depending on size and composition (Figs. 77-37 and 77-38). As with cholelithiasis, nonshadowing stones may be difficult to differentiate from aggregates of sludge or soft tissue masses. Improved accuracy can be accomplished with the use of endoscopic ultrasound,¹⁶⁷ but this is more invasive and operator dependent.

Computed Tomography

Unenhanced conventional CT has a sensitivity of 75% in the detection of choledocholithiasis.¹⁶⁸⁻¹⁷⁰ Indirect signs, such as ductal dilation and abrupt termination of the duct, may be useful but are not conclusive. Multidetector CT (MDCT) has a higher sensitivity, ranging from 65% to 88%.¹⁷¹⁻¹⁷⁴ Multiplanar reconstruction coronal images through the CBD may be useful in depicting stones (Fig. 77-39; see also Fig. 77-37C). In specifically evaluating for choledocholithiasis, water should be used to opacify the bowel because positive oral contrast material may obscure visualization of distal CBD stones and fill perivaterian duodenal diverticula. In a study comparing MDCT and ERCP for the detection of CBD calculi, CT had a sensitivity of 88%, specificity of 97%, and accuracy of 94%.¹⁷¹ Bile window settings (adjustment of the window level setting to the mean attenuation of the CBD and the window width to 150 HU) improve visualization of noncalcified stones by creating better contrast between bile and soft tissues.

The CT appearance of CBD stones is variable. Depending on their composition, stones may be calcified or soft tissue or low density with respect to bile. Calcified stones are the most readily identified (Fig. 77-40A). Unenhanced images are better for detection as most stones are slightly hyperdense. Four CT criteria for detection of CBD stones are (1) a target sign, which refers to a central density, corresponding to the stone, surrounded by hypoattenuating bile or ampullary soft tissue; (2) the rim sign, which corresponds to a faint rim of increased density along the margin of a low-density area (Fig. 77-40B); (3) the crescent sign, which refers to a calculus with increased density surrounded by a crescent of hypoattenuating bile (Fig. 77-40C); and (4) indirect signs, which include abrupt

Figure 77-37 Choledocholithiasis: ultrasound and CT features. **A.** Sagittal image demonstrates common bile duct (cbd) dilation. There is an intraductal echogenic shadowing focus (arrow), consistent with a large stone. **B.** Axial contrast-enhanced CT demonstrates increased density in dilated common bile duct (arrow) consistent with stones. g, Gallbladder. **C.** CT image reformatted in coronal plane. Multiple stones in the dilated duct (white arrow). Black arrow, Intrahepatic biliary dilation.

Figure 77-38 Choledocholithiasis: ultrasound and CT findings. **A.** Ultrasound demonstrates dilated common bile duct (cbd) with small stone located distally (arrow). Note posterior acoustic shadowing (arrowhead). **B.** Contrast-enhanced CT demonstrates small distal stone (arrow) that was not identified prospectively.

termination of a dilated distal CBD without visible surrounding mass or biliary dilation.¹⁶⁸ By use of these criteria, 76% of stones were detected in one series.¹⁶⁸ The investigator found that abrupt termination of the CBD without soft tissue mass was most often associated with pancreatic carcinoma; CBD stones manifested either as a densely calcified object or as a target sign.

CT cholangiography is redefining the role of CT as a technique for visualizing the biliary tract and choledocholithiasis. MDCT is performed after indirect opacification of the biliary tract with oral or intravenous iodinated cholangiographic agents.^{175,176} Improved z-axis resolution is achieved with multi-detector array scanners and high-resolution reconstructions of the biliary tract.¹⁷⁷ In one series, CT cholangiography was shown to provide excellent visualization of biliary anatomy and

filling defects, with 95% sensitivity for choledocholithiasis.¹⁷⁸ Other more recent series also show promise of these techniques in evaluation of choledocholithiasis.¹⁷⁹⁻¹⁸² A major drawback of this technique is the associated risk of allergic reactions induced by contrast material.¹⁸³ At the author's institution, this technique is currently used primarily to define donor biliary anatomy before liver transplantation and does not play a role in evaluation of choledocholithiasis.

Magnetic Resonance Imaging

MRCP was introduced in the 1990s as a noninvasive and low-risk technique to evaluate the biliary system and is an excellent modality for the detection of CBD stones.^{184,185} Reported sensitivity, specificity, and accuracy of MRCP for choledocholithiasis

Figure 77-39 Choledocholithiasis: CT appearance. **A.** There are multiple small stones in gallbladder with dilation of CBD (arrow). **B.** More caudal image demonstrates small stone at level of ampulla (arrow). **C.** Coronal reformatted image shows CBD stone (arrow).

Figure 77-40 Choledocholithiasis: various appearances at CT. **A.** Calcified stone (arrow) in CBD. **B.** Rim calcified stone (arrow) in CBD. There is peripancreatic inflammatory change (arrowhead) due to acute pancreatitis. **C.** Soft tissue density noncalcified stone (arrow) in CBD with low-density crescent of bile.

range from 85% to 100%, 90% to 90%, and 89% to 97%, respectively.^{186,187} MRCP has been shown to be more sensitive than ultrasound and CT²¹ for the detection of CBD stones and is highly accurate for the detection of CBD stones in patients with symptomatic gallstones.¹⁸⁷ The MRCP technique is discussed more fully in Chapter 75.

Thin-slice (3 or 4 mm) half-Fourier acquisition single-shot turbo spin-echo (HASTE) sequences, also referred to as half-Fourier rapid acquisition with relaxation enhancement (RARE), allow rapid acquisition, with imaging of the biliary tract in a single breath hold, decreasing motion artifact.^{186,188-190} Conventional unenhanced T1- and T2-weighted MR images are also usually performed. Gadolinium-enhanced images are helpful if neoplasm or inflammatory disease is suspected.¹⁹⁰ High-resolution fat-suppressed T1-weighted three-dimensional gradient-echo sequences allow high-resolution images of the biliary tree that can be reconstructed in any plane. Additional techniques include the use of contrast agents that are taken up by hepatocytes and excreted through the biliary system, such as manganese dipyrroxy diphosphate, and the use of oral contrast agents, such as ferumoxsil (GastroMark; Mallinckrodt, Maryland Heights, MO), or diluted intravenous contrast material, such as gadopentetate dimeglumine (Magnevist; Berlex Laboratories, Wayne, NJ). Pineapple juice, which has a high manganese content, can also be used to decrease signal from hyperintense bowel fluid.¹⁸⁶ Recently, three-dimensional T2-weighted turbo spin-echo is also promising and offers improved anatomic accuracy, higher signal-to-noise ratio, and thinner sections without gaps.¹⁹¹⁻¹⁹³ When it is combined with new techniques, such as parallel acquisition technique, data acquisition time is shortened while spatial resolution and contrast are retained.¹⁹⁴ Faster gradients and navigator-based respiratory triggering also allow improved image quality.¹⁸⁶

AT MRCP, stones will generally appear as well-circumscribed low signal intensity filling defects in the biliary tract (Fig. 77-41). MRCP can detect stones as small as 2 mm²¹ and may be a helpful adjunct to ultrasound and CT when biliary calculi are suspected but not definitively visualized (Fig. 77-42). MRCP may also be helpful if a noncalcified stone is difficult to differentiate from a soft tissue mass. Diagnostic pitfalls include gas,

blood, and other abnormality within the duct simulating stones as well as signal loss due to surgical clips after cholecystectomy. High signal from adjacent fluid collections, ascites, or edema may also interfere with biliary signal. Pseudo-obstruction of the extrahepatic bile duct may be caused by arterial pulsatile compression, most commonly at the common hepatic duct, by the right hepatic artery,¹⁹⁵ and flow artifacts may mimic filling defects.¹⁹⁶ It is important to review coronal source and transverse T2-weighted images to avoid these pitfalls.

Intrahepatic Biliary Calculi

RECURRENT PYOGENIC CHOLANGITIS

The presence of calculi within the intrahepatic bile ducts is uncommon in patients with gallstones. This can occur in the setting of biliary strictures with long-standing obstruction, such as after biliary surgery or in the setting of Caroli's disease.¹⁹⁷ In the Asian population, the most common entity associated with the formation of primary intrahepatic stones is recurrent pyogenic cholangitis, also referred to as Oriental cholangiohepatitis. This is an endemic disease in Southeast Asia that is more frequently encountered in the United States because of increased immigration from Asia.^{198,199} The hallmark features of this disorder include pigment stone formation within the intrahepatic and extrahepatic bile ducts, stricture development, and biliary dilation. This disorder is characterized clinically by recurrent attacks of fever, chills, jaundice, and abdominal pain. The cause of this disorder is not entirely clear, although it is postulated that infection of the biliary tract with parasitic organisms such as *Clonorchis sinensis* results in biliary stasis and stone formation. Ultimately, there is progression to stricture formation, biliary obstruction, and hepatic cirrhosis with an increased risk of cholangiocarcinoma.

IMAGING

Although imaging of this disorder has traditionally been performed with invasive cholangiographic methods, noninvasive cross-sectional imaging techniques, including CT, ultrasound,

Figure 77-41 Choledocholithiasis: MR findings. A. T2-weighted coronal HASTE image shows low signal intensity CBD stones (arrows). **B.** Two-dimensional thick-slab image demonstrates stones (arrows).

Figure 77-42 Choledocholithiasis: imaging features. An 80-year-old woman with right upper quadrant pain. **A.** CT shows small density suggestive of stone in distal CBD (arrow). **B.** Coronal T2-weighted HASTE MR image confirms the presence of stones in the distal duct (arrow). **C.** Stones (arrow) demonstrated on two-dimensional thick-slab MR image. **D.** ERCP confirms stone (arrow). Sphincterotomy and stone retrieval were performed.

and MRI, now play a more important role.²⁰⁰⁻²⁰⁴ Ultrasonography is usually the initial imaging modality and demonstrates intrahepatic and extrahepatic biliary dilation, with intrahepatic stones that may or may not shadow (Fig. 77-43A). A nonshadowing stone may mimic an echogenic soft tissue mass. CT provides more complete evaluation of the full extent of disease and associated complications, such as liver abscess and pancreatitis (Fig. 77-43B). CT can be particularly helpful if the patient has already undergone biliary enteric bypass surgery, in which case associated pneumobilia may obscure findings at sonography. Noncontrast images may be helpful to identify noncalcified pigment stones that are soft tissue density²⁰⁰ (Fig. 77-44). The use of intravenous contrast agents allows better detection of complications, such as cholangitis, with improved visualization of ductal wall and periductal enhancement indicating active infection or inflammation²⁰² as well as abscess formation (Fig. 77-45). The left hepatic lobe, particularly the lateral segment, most often shows biliary dilation and stone disease. This is an important distinguishing feature of this disorder. Chronic findings include segmental lobe atrophy involving the lateral left lobe, portal vein thrombosis, and ultimately changes of

cirrhosis. Hepatic atrophy has been shown to correlate with portal vein occlusion and is usually most prominent in the lateral segment of the left lobe.²⁰⁵ MR and MRCP methods have also proved useful in the identification of intrahepatic biliary calculi and associated parenchymal abnormalities.²⁰¹

Other Conditions Related to Gallstones

SPILLED GALLSTONES AFTER LAPAROSCOPIC CHOLECYSTECTOMY

Gallbladder perforation during laparoscopic cholecystectomy is reported to occur in 10% to 40% of cases, with spillage of gallstones occurring less frequently, approximately 6% to 8% of the time.²⁰⁶ This complication occurs more frequently during surgery for an acutely inflamed gallbladder and may occur during dissection of the gallbladder from the hepatic bed or removal through the umbilical incision. Late abscess formation due to spilled stones is rare, with an incidence of less than 1%,²⁰⁷⁻²⁰⁹ occurring more frequently when spillage of both bile

Figure 77-43 Recurrent pyogenic cholangitis. **A.** Hepatic ultrasound demonstrates cast of stones in intrahepatic ducts of left lateral segment (arrows). These appear as echogenic material with posterior acoustic shadowing. **B.** Contrast-enhanced CT demonstrates soft tissue density material in dilated ducts (arrows) corresponding to pigment stones. The lateral segment is primarily involved, a typical feature of recurrent pyogenic cholangitis.

Figure 77-44 Recurrent pyogenic cholangitis: utility of noncontrast CT. **A.** Precontrast CT scan shows cast of stones in dilated intrahepatic ducts (arrows). **B.** After intravenous administration of contrast material, stones are less conspicuous.

Figure 77-45 Recurrent pyogenic cholangitis with abscess. **A.** CT scan obtained during portal venous phase demonstrates stones in dilated intrahepatic ducts of left lateral segment (black arrows). There is an abscess with fluid attenuation in the liver parenchyma (white arrow). **B.** Scan obtained during the arterial phase demonstrates increased contrast enhancement around the abscess (arrow) related to hyperemia (transient hepatic attenuation difference).

and calculus occurs. Infectious complications are more likely to occur with bilirubinate stones because they contain viable bacteria. The spilled stones may remain in the peritoneal cavity adjacent to the liver and cause a subhepatic abscess or abscess in the retroperitoneum below the subhepatic space. However, because of pneumoperitoneum and peritoneal irrigation at the time of laparoscopy, stones may also migrate to distant sites. More unusual locations for abscess formation include the pleural space, the abdominal wall at the trocar site, and within an incisional hernia. Because of the indolent nature of the infection, the time interval for presentation after surgery is variable, ranging from 1 month to 10 years, with a reported peak incidence around 4 months.²⁰⁶ The patient usually presents with vague constitutional symptoms, such as nausea, anorexia, and low-grade fever.

Ultrasound, CT, and MRI are effective in identifying the abscess and associated dropped gallstones. The abscess appears as a thick-walled fluid collection, most commonly located posterior to the right lobe of the liver (Fig. 77-46). Stones appear as echogenic foci on ultrasound and as calcified densities at CT. At MRI, stones may be identified as low signal intensity foci on T2-weighted images. In a series of five patients by Morrin and associates,²¹⁰ the diagnosis of abscess formation secondary to dropped stones was made in only two of five patients prospectively by a combination of imaging modalities. In retrospect, however, the diagnosis could be made in all patients. Recognizing the history of prior laparoscopic cholecystectomy and careful search for spilled stones, particularly when an abscess is identified in the subhepatic space, are important in making the diagnosis. The abscess may be misdiagnosed as tumor or abscess from another cause if the stones are not radiopaque or not recognized or if they are located in an atypical location (Fig. 77-47). If stones are found in other locations, such as the pelvis, the presence of clips in an otherwise empty gallbladder fossa may help confirm the diagnosis (Fig. 77-48). Surgical or percutaneous removal of the stones is necessary for complete cure as infected stones cannot be sterilized with antibiotic therapy.^{211,212}

MIRIZZI SYNDROME

Mirizzi syndrome refers to common hepatic duct or CBD obstruction due to extrinsic compression from an impacted gallstone in the gallbladder neck or cystic duct or from associ-

ated inflammatory changes. This may be complicated by a cholecystocholedochal fistula.²¹³⁻²¹⁵ Mirizzi syndrome is an uncommon complication of long-standing cholelithiasis; the usual clinical presentation is recurrent episodes of jaundice and cholangitis. This syndrome is reported in up to 2% of patients operated on for symptomatic gallstone disease.²¹⁶ Preoperative diagnosis is important because standard cholecystectomy technique is associated with an increased risk of extrahepatic bile duct injury secondary to dense fibrosis and edema around the hepatoduodenal ligament.²¹⁷

Mirizzi syndrome may be diagnosed with ultrasound, CT, or MRI.^{218,219} The hallmark is intrahepatic biliary dilation and dilation of the common hepatic duct to the level of the porta hepatis with normal caliber of the more distal CBD. A stone may be identified in the gallbladder neck or cystic duct (Fig. 77-49). Multiplanar reconstruction imaging with either CT or MR can be particularly helpful to identify the extrinsic nature of the obstruction. MRI has been proposed as most useful for demonstrating dilation of the intrahepatic ducts, level of obstruction, and location of gallstones.²¹⁹

GALLSTONE ILEUS

Gallstone ileus is mechanical obstruction of the bowel by an impacted gallstone and results from perforation of the gallbladder and fistula formation between the gallbladder and an adjacent viscus. Fistula formation most commonly occurs between the gallbladder and duodenum, followed by the colon and stomach.^{3,220} Obstruction usually occurs in the small intestine when a gallstone larger than 2.5 cm lodges in the lumen. The most common sites of gallstone impaction are the ileum (54%-65%), the jejunum (27%), and the duodenum (1%-3%).²²¹ The term *Bouveret's syndrome* refers to proximal gallstone impaction resulting in duodenal or pyloric obstruction. Gallstone ileus accounts for approximately 1% to 5% of all cases of nonmalignant small bowel obstruction, increasing up to 25% in patients older than 65 years.²²¹

Less than half of patients presenting with gallstone ileus have a known history of preexisting gallbladder disease. Patients usually present with clinical symptoms of bowel obstruction, and abdominal radiography may be the initial imaging study performed. The classic triad of findings, referred to as Rigler's triad,²²² includes presence of bowel obstruction, pneumobilia,

Figure 77-46 Spilled gallstones after laparoscopic cholecystectomy. **A.** Contrast-enhanced CT obtained before surgery demonstrates multiple calcified stones in thick-walled gallbladder (arrow) with pericholecystic fluid, indicating acute cholecystitis. **B.** CT obtained 1 year after cholecystectomy when the patient returned with right upper quadrant pain demonstrates abscess posterior to the right hepatic lobe containing spilled stones (arrows).

Figure 77-47 Spilled gallstones after laparoscopic cholecystectomy with perinephric abscess. **A.** Initial contrast-enhanced CT demonstrates multiple calcified stones in gallbladder neck (arrow). **B.** Six months after laparoscopic cholecystectomy, the patient returned with right upper quadrant and flank pain. An abscess with retained stones (arrow) is identified posterior to the right hepatic lobe. **C.** Stones had also migrated to perinephric space (arrow), causing a perinephric abscess.

Figure 77-48 Spilled gallstones after laparoscopic cholecystectomy with stones located in the pelvis. **A.** Contrast-enhanced CT demonstrates two partially calcified stones in the pelvis (arrows). A surgical clip is also noted. **B.** Clips are present in the otherwise empty gallbladder fossa, compatible with prior cholecystectomy.

Figure 77-49 Mirizzi syndrome: imaging features.

A. Ultrasound demonstrates large gallstone in gallbladder neck (arrow) associated with intrahepatic biliary dilation (arrowhead). **B.** Axial T2-weighted HASTE MR image demonstrates the large stone in the gallbladder neck (arrow) as well as the intrahepatic biliary dilation. **C.** Coronal T2-weighted HASTE MR image demonstrates stone (arrow), which is located outside of the CBD (arrowhead).

and the obstructing gallstone. However, this is visualized in only 30% to 35% of patients²²³ (Fig. 77-50). CT is frequently used to evaluate patients with bowel obstruction to confirm diagnosis, to determine etiology of obstruction, and to evaluate for complications. CT is superior to plain abdominal radiography for visualization of the obstructing gallstone and detection of small amounts of gas in the gallbladder and biliary tree^{221,224-226} (Fig. 77-51). The cholecystenteric fistula may also be demonstrated. Cholecystenteric fistula may develop in the absence of gallstone ileus, usually resulting from chronic gallbladder inflammation. CT findings include a contracted gallbladder containing air and visualization of a fistulous track (Fig. 77-52).

Hyperplastic Cholecystoses

The term *hyperplastic cholecystoses* was introduced in 1960 by Jutras²²⁷ to designate a spectrum of gallbladder abnormalities separate from inflammatory disease. Hyperplastic refers to a benign proliferation of normal tissue elements, and cholecystoses are pathologic processes distinct from inflammation.²²⁸ The two major conditions within this spectrum of disorders are cholesterosis and adenomyomatosis.

CHOLESTEROSIS

Pathogenesis and Epidemiology

Cholesterosis results from the accumulation of neutral lipid, in particular cholesterol esters and triglyceride, within

macrophages in the lamina propria of the gallbladder.² The cholesterol is probably deposited in the epithelium initially, accumulates in the lamina propria, and subsequently is taken up by the macrophages.²²⁸ The accumulation of lipid creates yellow excrescences on the surface of the mucosa that can be seen by the naked eye. Associated hyperemia of the mucosa gives the appearance of a strawberry, and the term *strawberry gallbladder* has been used to describe the appearance of the gallbladder in this disorder.²²⁹ The pathogenesis of this disorder is not completely understood. Altered hepatic cholesterol synthesis may play an etiologic role leading to increased cholesterol levels in the bile.²³⁰ Impaired cholesterol transport out of the mucosa may also play a role. This disorder is not associated with cholesterol gallstones, hyperlipidemia, or atherosclerosis. There may be an increased incidence of gallstones, present in 50% in one surgical series.²³¹ In an autopsy study involving 1319 cases, there were 165 cases of cholesterosis for an incidence of 12.5%.²³² There are no specific clinical findings, and presentation is usually the result of a complicating disorder, such as cholelithiasis or cholecystitis.

On pathologic examination, cholesterosis is defined by the deposition of lipid within the gallbladder mucosa in one of four patterns: (1) diffuse involvement (80%); (2) cholesterol polyps resulting from focal excrescences of lipid-containing epithelium projecting into the gallbladder lumen, usually measuring 2 to 10 mm; (3) combined diffuse and polypoid form (10%); and (4) focal cholesterosis with only a portion of the gallbladder affected.²³³ Cholesterol polyps account for 60% to 90% of

Figure 77-50 Gallstone ileus: Bouveret's syndrome. **A.** Abdominal radiograph demonstrates dilated, gas-filled stomach (S). Rounded calcified density (arrowhead) represents a large stone in the region of the distal gastric antrum. There is pneumobilia (arrow). The presence of bowel obstruction, pneumobilia, and obstructing gallstone constitutes Rigler's triad. **B.** Oral and intravenous contrast-enhanced CT demonstrates distended, contrast-filled stomach (g) consistent with gastric outlet obstruction. There is oral contrast material and bubbles of air in gallbladder fossa (arrow) consistent with cholecystenteric fistula. **C.** Slightly more inferior CT image demonstrates large obstructing gallstone (arrow) within the proximal duodenum. Air is also present in the CBD (arrowhead). **D.** Upper gastrointestinal series demonstrates stone as large filling defect that has migrated to duodenal-jejunal junction (white arrow). Fistula between the gallbladder and proximal duodenum is also demonstrated (black arrow).

gallbladder polyps and are not true neoplasms.² They may be solitary but are most commonly multiple. At histologic evaluation, the polyp has a vascular connective tissue stalk and a branching villous or complex papillary pattern; however, foamy macrophages within the lamina propria are the dominant cellular component.²

Imaging

The diffuse form of cholesterosis cannot be diagnosed at imaging. Traditionally, oral cholecystography was used to diagnose the polypoid variety, which appears as numerous fixed filling defects in the lumen of the gallbladder. As this technique is no longer widely performed, findings are now apparent primarily at sonography. Cholesterol polyps may appear as single or multiple nonshadowing foci adherent to the gallbladder wall and projecting into the gallbladder lumen (Fig. 77-53). Gallbladder polyps may also be visible at CT (Fig. 77-54). It is estimated that polypoid lesions of the gallbladder are seen in approximately 1.4% to 7% of the adult population undergoing abdominal sonography.^{234,235} When polypoid lesions in the gallbladder are identified at either ultrasound or CT, small (<1 cm) and multiple, the diagnosis of benign cholesterol polyps is most likely.²³⁶ The management of gallbladder polyps detected at

imaging remains somewhat controversial. Initial 3- to 6-month ultrasound follow-up can be performed for 1 to 2 years to ensure stability, and this approach has been advocated by many. A study evaluating 346 patients with incidentally detected gallbladder polyps at ultrasound with ultrasound follow-up in 149 patients, 42 patients with cholecystectomy, and 155 patients with clinical follow-up concluded that the incidence of neoplasm in gallbladder polyps 6 mm or smaller is negligible and that these polyps require no further follow-up.²³⁷ Others have proposed that follow-up may not be necessary for polyps of 5 mm or smaller.²³⁸ However, when polyps are single, are larger than 10 mm, are sessile, occur in individuals older than 50 years, or demonstrate interval increase in size during surveillance, differentiation from other polypoid neoplasms such as adenomas or primary or metastatic neoplasm is not possible and surgical evaluation may be required.²³⁸⁻²⁴⁰ In a surgical series of gallbladder polypoid lesions, with use of size larger than 10 mm, a 100% sensitivity and 86.95% specificity in the diagnosis of malignant disease were achieved.²⁴¹ A more recent surgical series recommended that ultrasound size larger than 9 mm, ultrasound suggestion of invasion at the liver interface, and wall thickening of more than 5 mm, especially in the presence of gallstones, should increase suspicion of malignant disease.²³⁵

Figure 77-51 Gallstone ileus. **A.** CT demonstrates dilated fluid-filled small bowel (s). There is a partially calcified gallstone at the point of transition in the right lower quadrant (arrow). **B.** CT image of upper abdomen demonstrates collapsed gallbladder (arrow). The stomach (s) is dilated and fluid filled. **C.** Slightly more inferior image demonstrates air in the CBD (arrow).

Figure 77-52 Cholecystoduodenal fistula secondary to chronic cholecystitis. **A.** CT demonstrates contracted gallbladder containing air (black arrow). There is also air in the CBD (white arrow). **B.** Upper gastrointestinal series demonstrates fistula between gallbladder and proximal duodenum (arrow).

ADENOMYOMATOSIS

Pathogenesis and Epidemiology

Adenomyomatosis of the gallbladder, also referred to as adenomyomatous hyperplasia and intramural diverticulosis, is an acquired, hyperplastic lesion of the gallbladder characterized by excessive proliferation of surface epithelium with invaginations into the thickened, hypertrophied muscularis

propria.²³³ The intramural diverticula formed by epithelial invaginations into the muscularis are referred to as Rokitansky-Aschoff sinuses (RAS), and dilated RAS are a prominent feature of this disorder. The pathophysiologic mechanism of this disorder is not entirely certain. It is not usually associated with cholesterosis, indicating a separate pathophysiologic process. Pathogenesis has been postulated to result from mechanical obstruction of the gallbladder (from stones,

Figure 77-53 Cholesterol polyps: ultrasound and pathology findings. **A.** Sagittal ultrasound image demonstrates two echogenic nonshadowing foci (arrows) adherent to the posterior wall of the gallbladder (g), consistent with cholesterol polyps. **B.** Specimen image in a different patient demonstrates a diffuse granular pattern of cholesterosis with several cholesterol polyps.

Figure 77-54 Cholesterol polyp: CT. CT demonstrates polypoid excrescence arising from the gallbladder wall (arrow).

cystic duct kinking, or congenital septum), chronic inflammation, and anomalous pancreaticobiliary ductal union.²³³ The functional obstruction to bile outflow causes increased pressure within the gallbladder lumen and results in invagination of the mucosa through the muscularis, forming the dilated RAS. The reported incidence of adenomyomatosis in cholecystectomy specimens is up to 8%.²⁴² The association of this disorder with clinical findings is controversial. The disorder may be asymptomatic or associated with symptoms of chronic cholecystitis. More than 90% of cases are associated with gallstones, which may be responsible for biliary symptoms.² Adenocarcinoma of the gallbladder has been found in association with adenomyomatosis; however, a causal link has not been established.²³³ In a surgical series of 3000 resected gallbladders, there was a higher frequency of gallbladder carcinoma (6.4%) in gallbladders with segmental adenomyomatosis than in those without.

Adenomyomatosis may be generalized, segmental, or focal, and the focal form is most common.²⁴³ Diffuse adenomyomatosis causes thickening and irregularity of the mucosa

and muscle layer with associated RAS, which on gross inspection appear as collections of bile in the gallbladder wall. In the segmental or annular form, a focal circumferential stricture divides the gallbladder lumen into separate compartments. The focal form, which causes a focal mass or nodule, usually is fundal in location, frequently referred to as an adenomyoma.

Imaging

In the past, oral cholecystography played an important role in the diagnosis of adenomyomatosis.²²⁸ The hallmark of this disorder is the filling of intramural diverticula with contrast material, which are manifested as radiopaque dots that parallel the gallbladder lumen. In the fundal form, findings may mimic a polyp or other mass. The segmental form may be manifested as circumferential narrowing of the lumen.

Ultrasound. The ultrasound findings in adenomyomatosis have been well described and include diffuse or segmental thickening of the gallbladder wall and anechoic intramural diverticula.²⁴⁴⁻²⁴⁷ Biliary sludge or gallstones within the diverticula may appear as echogenic foci.^{244,247} A V-shaped reverberation or comet-tail artifact may emanate from small cholesterol stones that are lodged in the RAS (Fig. 77-55). This artifact is a result of sound reverberating within or between cholesterol crystals²⁷ and helps differentiate gallbladder wall thickening related to adenomyomatosis from other abnormalities (Fig. 77-56A). The use of high-resolution transducers has been shown to increase detection of intramural cysts or echogenic foci, enabling a more confident diagnosis of adenomyomatosis.²⁴⁸ An additional diagnostic clue is the presence of color Doppler twinkling artifacts in the gallbladder wall that probably result from calcifications or cholesterol depositions with rough interfaces present in the RAS^{249,250} (see Fig. 77-55C, D). This feature may be better demonstrated with a lower frequency transducer.²⁵¹ If these features are not identified, there may be nonspecific thickening of the gallbladder wall. This mural thickening may be indistinguishable from acute or chronic cholecystitis or gallbladder carcinoma on the basis of imaging; therefore, knowledge of the clinical setting is essential. The segmental form of adenomyomatosis results in annular narrowing, usually of the body of the gallbladder, with resulting compartmentalization or segmentation of the gallbladder lumen. In this setting,

Figure 77-55
Adenomyomatosis: ultrasound and pathologic features.
A. Ultrasound demonstrates multiple comet-tail artifacts (arrows) arising from the wall of the gallbladder (g). **B.** Histologic specimen in a different patient demonstrates debris in a Rokitansky-Aschoff sinus. **C.** Comet-tail artifacts are present only in the superior aspect of the gallbladder in this patient with segmental adenomyomatosis (arrows). **D.** Color Doppler demonstrates twinkling artifact (arrows).

Figure 77-56 **Diffuse adenomyomatosis.**
A. Ultrasound demonstrates diffuse thickening of gallbladder (g). There are echogenic foci in the wall (arrow) with associated comet-tail artifact. **B.** Contrast-enhanced CT demonstrates thickening gallbladder wall (arrow) with intramural regions of low attenuation. **C.** Axial T2-weighted HASTE image demonstrates thickened gallbladder wall with multiple high signal intensity areas (arrows) corresponding to the dilated Rokitansky-Aschoff sinuses.

the fundal compartment may be overlooked. Stones are often trapped within this fundal compartment and are not readily visualized. Again, if the reverberation artifact is not observed, this focal mural thickening may be indistinguishable from gallbladder carcinoma (Fig. 77-57A). The focal form of adenomyomatosis most commonly appears as a sessile, polypoid mass in the region of the fundus, protruding into the gallbladder lumen (Fig. 77-58A). This may mimic other gallbladder masses, including neoplasm. Coexisting gallstones are a frequent finding, with increased incidence in patients with the segmental form.²⁵²

Computed Tomography. On CT, the diffuse form of gallbladder adenomyomatosis is manifested with gallbladder wall thickening and visualization of intramural diverticula^{245,253,254} (see Fig. 77-56B). The segmental and focal forms can be particularly difficult to differentiate from carcinoma because they appear as

focal thickening of the gallbladder wall or a fundal intraluminal mass (Figs. 77-57B and 77-58B). A study addressing the CT differentiation of adenomyomatosis and gallbladder cancer concluded that the diagnosis of adenomyomatosis can be made with reasonable accuracy when diffuse or focal thickening of the gallbladder wall is seen in association with small cystic-appearing spaces.²⁵⁵ In this study, specificity for diagnosis of adenomyomatosis ranged from 79% to 93%. When the findings at CT are not diagnostic, follow-up with ultrasound is necessary. The advantage of ultrasound is that the reverberation artifact related to the RAS may be demonstrated. This finding is not seen with adenocarcinomas. However, small RAS may be overlooked.²⁵³

Magnetic Resonance Imaging. MR has been shown to serve as a helpful problem-solving tool in patients with

Figure 77-57 Annular/segmental adenomyomatosis. **A.** Sagittal ultrasound image of the gallbladder (g) demonstrates focal thickening in the midportion of the gallbladder (arrow), resulting in compartmentalization. Echogenic foci with ring-down artifact are noted at this location, which helps exclude other causes of focal gallbladder wall thickening, such as carcinoma. **B to D.** Sequential CT images in a second patient from the level of the gallbladder fundus to neck demonstrate focal mural thickening at the midportion of the gallbladder in the area of focal adenomyomatosis (white arrow). There are two compartments of the gallbladder: one in the region of the fundus (black arrow), and one in the region of the neck (arrowhead). **E.** Coronal T2-weighted HASTE image in a third patient demonstrates compartmentalization of the gallbladder with annular narrowing at midportion, resulting in two compartments (arrowhead and black arrow). Low signal intensity filling defect in the fundal compartment (arrowhead) corresponds to a trapped stone in the fundal compartment. At point of narrowing, there are high signal intensity foci (white arrow) corresponding to the dilated Rokitsky-Aschoff sinuses.

Figure 77-58 Focal fundal adenomyomatosis. **A.** Sagittal ultrasound image of the gallbladder (g) demonstrates focal fundal thickening (arrow) with multiple comet-tail artifacts. **B.** CT in a different patient demonstrates a nodule (arrow) in the region of the fundus of the gallbladder (g). There is a low-attenuation area centrally corresponding to dilated Rokitansky-Aschoff sinus. **C.** Coronal T2-weighted HASTE MR image in a third patient demonstrated multiple high signal intensity foci (arrow) in the region of the fundus of the gallbladder (g) corresponding to the dilated Rokitansky-Aschoff sinus. This has been referred to as the string of pearls sign.

gallbladder adenomyomatosis.⁶⁴ The demonstration of RAS on T2-weighted images is critical in diagnosis of this disorder.²⁵⁶ These appear as high signal intensity foci in the gallbladder wall (Figs. 77-56C, 77-57E, and 77-58C). In a study comparing ultrasound, CT, and MRI,²⁵⁷ MRI using a half-Fourier RARE sequence was superior to helical CT and trans-abdominal ultrasound in establishing the diagnosis of adenomyomatosis. Helical CT showed most lesions as a thickened wall or mass, with limited ability to delineate the RAS. MRI was found to have an accuracy of 93% versus 75% for CT and 66% for ultrasound. MRI offers more complete visualization of the gallbladder and more definitive identification RAS. Yoshimitsu and colleagues²⁵⁶ also found a higher sensitivity of MRI for detection of the RAS in the thickened gallbladder wall and referred to this finding as the “string of pearls” sign (see Fig. 77-58C). The specificity of this sign for adenomyomatosis is 92%, helpful in the differentiation from gallbladder carcinoma, in which this sign is never observed. If findings on ultrasound are equivocal, MR with MRCP is the next best test. There is an increased incidence of gallbladder carcinoma reported in patients with segmental adenomyomatosis²⁴²; therefore, these patients should be closely observed.

Acute cholecystitis may occur in a gallbladder with adenomyomatosis, and there may be overlap in imaging features, such as wall thickening. If ultrasound findings are equivocal, cross-sectional imaging with CT or MR, which

may demonstrate additional features, such as hyperemia in the adjacent liver, may be used as a problem-solving tool (Fig. 77-59).

Milk of Calcium Bile

When the cystic duct is obstructed by a gallstone, the gallbladder may become chronically inflamed, filling with a putty-like material consisting of calcium carbonate. This dense material can be visualized on abdominal plain films (Fig. 77-60) and CT.

Gallbladder Hydrops

Massive enlargement of the gallbladder can develop proximal to an obstructing stone in the gallbladder neck or cystic duct. If there is no supervening infection, the gallbladder lumen becomes progressively distended from the accumulation of sterile mucus secreted by the epithelial cells (Fig. 77-61). The patient usually has few symptoms but may have chronic right upper quadrant discomfort. A right upper quadrant mass may be palpable.

Plain radiographs may show a right upper quadrant mass indenting the lateral border of the duodenum. Sonography shows a distended gallbladder (>5 cm) with a biconvex shape and normal wall thickness. Sludge may be present. CT shows lumen distention and normal mural thickness.

Figure 77-59 Segmental adenomyomatosis with associated acute cholecystitis. A. Contrast-enhanced CT demonstrates focal gallbladder wall thickening and stone in the fundal compartment (*arrow*). **B.** There is hyperemia in the adjacent liver, compatible with active inflammation, helping to confirm diagnosis of acute cholecystitis (*white arrow*). The inferior portion of the gallbladder demonstrates normal wall thickness (*black arrow*).

Interventional Radiology of the Gallbladder and Biliary Tract

THOMAS A. FARRELL | MIKIN V. PATEL

CHAPTER OUTLINE

Preprocedural Management

Percutaneous Cholecystostomy

Technique

Percutaneous Gallbladder Aspiration

Acalculous Cholecystitis

Percutaneous Transhepatic Cholangiography and Drainage

Technique

Complications

Biliary Strictures

Malignant Stricture

Benign Stricture

Common Duct Stone Removal

Bile Duct Injury

Primary Sclerosing Cholangitis

Biopsy

Interventional radiology continues to play a key role in the management of patients with gallbladder and biliary tract disease. Advances in techniques and technologies have improved patient care with the availability of minimally invasive procedures that include percutaneous drainage, biopsy, and stone removal. Diagnostic procedures include percutaneous transhepatic cholangiography and intraluminal biopsy. Therapeutic procedures include percutaneous drainage-decompression of the biliary tree or gallbladder, dilation of a bile duct stenosis or surgical anastomosis, placement of endobiliary plastic or metallic stents, removal of gallstones, and, finally, percutaneous intraluminal treatment of biliary tumors. This chapter reviews the indications, techniques, outcomes, and recent advances of these interventional procedures in a multidisciplinary setting.

Preprocedural Management

The interventionalist should be familiar with the patient's history, notably previous interventions including surgery. A recent physical examination is useful in evaluating the patient's general condition and is necessary if moderate conscious sedation is being used, in which case the patient should be fasting for at least 6 hours. Review of previous imaging is also helpful for clarification of anatomy and prior procedures.

The clinical practice guidelines of the Society of Interventional Radiology attempt to define practice principles that

generally should assist in producing high-quality medical care. The membership of the Society of Interventional Radiology Standards of Practice Committee represents experts in a broad spectrum of interventional procedures from both the private and academic sectors of medicine, and as such they represent a valid expertise on preprocedural coagulation status and antibiotic prophylaxis.

A platelet count of 50,000/ μ L or lower requires a platelet infusion at the time of the interventional procedure.¹ We generally prefer a prothrombin time of 18 seconds or less and will recommend administration of vitamin K and fresh frozen plasma in the nonacute and acute settings, respectively, to achieve this. Cessation of warfarin and clopidogrel is recommended for 4 to 5 days before the procedure. Unfractionated heparin should be stopped at least 4 hours and low-molecular-weight heparin should be stopped at least 12 hours in advance of the procedure.²

Although the risk is low in nonobstructed ductal systems, infection is a significant contributor to morbidity and mortality, particularly in elderly or immunocompromised patients with gallbladder and hepatobiliary disease. We recommend prophylactic intravenous antibiotics in all patients undergoing procedures with few exceptions.³ Our preferred antibiotics are 1 g of ceftriaxone and 1.5 to 3 g of ampicillin/sulbactam. The hospital pharmacy and the infectious disease service are useful resources for appropriate antibiotic use.

Preprocedural verification and skin marking should be standard as part of the Universal Protocol.⁴ The Universal Protocol was created to address the continuing occurrence of wrong site, wrong procedure, and wrong person surgery in Joint Commission–accredited organizations. The three principal components of the Universal Protocol include a preprocedure verification, site marking as previously mentioned, and a time-out. A time-out for patient safety is called immediately before the procedure, which includes identifying the patient by name and the type and site of procedure to be done.⁵

Percutaneous Cholecystostomy

Acute cholecystitis is the most common cause of acute right upper quadrant pain and occurs in approximately one third of patients with gallstones. In most cases, the condition is due to calculous obstruction of the gallbladder neck or cystic duct, leading to increased intraluminal pressure and distention of the gallbladder.

Although early laparoscopic cholecystectomy is typically the preferred and definitive treatment for acute cholecystitis, the morbidity and mortality increase with the patient's age and complexity, and percutaneous cholecystostomy (PC) has been used as a temporizing and sometimes definitive therapy in high-risk patients. This is a minimally invasive method of

percutaneous placement of a drainage catheter in the gallbladder lumen under ultrasound and fluoroscopic guidance. A positive clinical response, which varies between 56% and 100%, is considered when there is a decrease in white blood cell count, defervescence, and decrease in the need for vasopressors. The risks of PC (bleeding, infection, and visceral perforation) are low. Mortality is associated mainly with the underlying medical conditions. PC can be followed by elective cholecystectomy at a later stage if the patient's condition permits or by expectant or conservative management in those with acalculous cholecystitis.

The earliest reports describing PC for the treatment of acute cholecystitis date back some 30 years.^{6,7} Since then, multiple relatively small and predominantly single-institution series have been published, collectively supporting a role for imaging-guided percutaneous gallbladder decompression in high-risk patients.⁸⁻¹²

In a review of Medicare data between 1994 and 2009, annual PC procedures increased by 567% (from 1085 to 7239). During the same period, laparoscopic cholecystectomy procedures increased by 3% (from 203,836 to 209,650), and open procedures declined by 73%.¹³ Clinical acceptance of PC and the availability and expertise of interventional radiologists have both contributed to an increased use of PC. Expanding the availability of PC may have acted as a "convenience factor" as well, lowering thresholds for use over time and thus contributing to PC's growth. Some growth is also attributable to an aging population with an increasing number of comorbidities.

Traditionally, it was believed that whereas percutaneous drainage represented a valuable intervention, secondary cholecystectomy was mandatory in cases of acute calculous cholecystitis.¹⁴ However, considering limited survival and a low recurrence rate of cholecystitis in elderly high-risk patients with acute cholecystitis, PC is increasingly being accepted as a definitive treatment, and cholecystectomy may not be necessary after resolution of the acute symptoms with gallbladder drain exchanges every 6 to 8 weeks.¹⁵⁻¹⁷

Without evidence from randomized controlled trials comparing PC with surgery in such populations, however, the optimal role and timing of PC remain unclear. Historically, PC has been used in higher risk, often elderly and critically ill patients. As a result, studies comparing the percutaneous technique with cholecystectomy have shared a retrospective study design and selection bias as they have not evaluated comparable groups. Abi-Haidar and colleagues¹⁸ described a 10-year cohort of patients who underwent both techniques. As in other studies, the PC patients were older, had higher American Society of Anesthesiologists classification, and had more comorbidities.¹⁹ Not surprisingly, they experienced more readmissions and complications and had a longer hospital stay. The Cochrane Database Review Group compared two randomized prospective studies, PC followed by early laparoscopic cholecystectomy versus delayed laparoscopic cholecystectomy (70 patients) and PC versus conservative treatment (86 patients), and concluded that the studies had high risk of bias.²⁰⁻²² There was no significant difference in overall morbidity between the two intervention groups. On the basis of available evidence from these randomized clinical trials, the Cochrane Review Group was unable to determine the role of PC in the clinical management of high-risk surgical patients with acute cholecystitis and expressed a need for adequately powered randomized clinical trials of low risk of bias.

Two patient populations deserve consideration for this procedure: those with critical illness and those with a high likelihood of conversion from a laparoscopic to an open procedure. In the case of critical illness, particularly patients who develop acute cholecystitis during an intensive care unit stay, PC has a continued role in light of evidence that emergency cholecystectomy in the critically ill is associated with higher mortality rates than cholecystectomy.²³

An international consensus panel of hepatobiliary surgeons defined the diagnostic criteria and severity assessment of acute cholecystitis as part of the Tokyo Guidelines (TG07) in January 2007. In the TG07, PC should be used in patients with grade II (moderate) cholecystitis only when they do not respond to conservative treatment and for patients with grade III (severe) disease. For patients with severe (grade III) disease, gallbladder drainage is recommended, followed by intensive care.

The updated Tokyo Guidelines 2013 (TG13) describe the surgical treatment for acute cholecystitis according to the grade of severity, the timing, and the procedure used for cholecystitis in a question-and-answer format using the evidence concerning surgical management of acute cholecystitis. Consequently, it was agreed that cholecystectomy is preferable early after admission. However, literature concerning the surgical treatment according to the grade of severity could not be quoted because there have been no publications on this topic, but the consensus was to perform percutaneous drainage when conservative treatment is failing. One prospective study showed that predictors for failure of conservative treatment are age older than 70 years, diabetes, tachycardia, and distended gallbladder at admission. Likewise, white blood cell count ($>15,000$ cells/mL), elevated temperature, and age older than 70 years were found to be predictors for the failure of conservative treatment at 24- and 48-hour follow-up.²⁴

The CHOCOLATE trial is a current randomized controlled, parallel-group, superiority multicenter trial in The Netherlands in which high-risk patients with acute calculous cholecystitis will be randomized to laparoscopic cholecystectomy or PC.²⁵

TECHNIQUE

Work-up includes review of the patient's clinical status and imaging. The authors use a combination of ultrasound and fluoroscopic guidance to place a locking pigtail catheter in the gallbladder by a modified Seldinger technique. Liberal use of subcutaneous lidocaine is recommended in addition to conscious sedation with intravenous midazolam and fentanyl. Typically, an 18-gauge needle is advanced percutaneously into the gallbladder, after which the track is dilated over a short Amplatz stiff guidewire (Cook Medical, Bloomington, IN) with 6F and 8F dilators, followed by placement of an 8F locking pigtail that is connected to gravity drainage (Fig. 78-1). Speed is of the essence during the procedure as bile leakage during dilator exchange and catheter placement may be very painful. Technique modifications include use of a transhepatic instead of a transperitoneal route because of a higher risk of complications due to drain dislocation and also the use of a single-stick or trocar method to access the gallbladder instead of the Seldinger technique. Intuitively, the trocar or single-stick technique should be less painful and is preferred by some to the Seldinger technique for catheter placement. However, we think that the trocar technique may be more difficult in patients whose gallbladders are small or thick walled.

Figure 78-1 Percutaneous cholecystostomy. **A.** Ultrasound confirms position of needle in the gallbladder. **B.** Placement of a guidewire in the gallbladder. **C.** Placement of 8F pigtail drain in the gallbladder. **D.** Tube check several days later confirms a gallstone in the gallbladder and patency of the cystic duct. The tube was capped, and the patient had a cholecystectomy.

We rarely inject more than a few milliliters of contrast material to confirm the location of the tube to avoid bacteremia. A tube check is better done within 5 to 7 days to evaluate for cystic and common duct patency, followed by capping of the tube to promote internal drainage.

Percutaneous Gallbladder Aspiration

Ultrasound-guided aspiration of gallbladder contents offers a less invasive and sometimes just as effective an alternative to percutaneous gallbladder drainage for acute cholecystitis. The procedure can be performed at the bedside under ultrasound guidance with either a 21- or 18-gauge needle and has two main advantages over PC. First, the quoted complication rate is lower because aspiration involves fewer steps than drainage and the needle is narrower than any drainage catheter placed. Second, the patient's comfort and convenience are better with aspiration as the presence of a drainage catheter and bag may be cumbersome. In certain situations, however, PC is preferable to gallbladder aspiration. Aspiration may not be technically feasible in patients with viscous bile. Also, because it does not provide

continuous drainage, gallbladder aspiration is inappropriate in patients in whom the indication for gallbladder drainage is to provide relief from a distal biliary obstruction.

In a meta-analysis of 11 studies comparing aspiration with PC, the clinical response to PC was slightly better compared with aspiration.²⁶ However, the complication rate of PC was also higher than that of aspiration, with 4 of the 11 studies in this review having a complication rate in the range of 10% to 23%, which is well above the threshold set by the Society of Interventional Radiology Standards Committee.²⁷

In one of these comparative studies, the authors recommended that aspiration should be the procedure of choice in high-risk patients, reserving PC as a salvage procedure if aspiration is technically or clinically unsuccessful.²⁸ Interestingly, almost one quarter of patients in this study did not show a clinical response within 72 hours of gallbladder aspiration and had a salvage PC. Using this approach of gallbladder aspiration with salvage PC, the authors avoided PC in 77% of patients while obtaining the overall positive clinical response rate close to that of PC.

Figure 78-2 One-stick percutaneous transhepatic biliary drainage (PTBD). **A.** The 22-gauge needle tip is advanced into an appropriate duct for conversion. AP, Anteroposterior view; LAT, lateral view. **B.** After removal of the stylet, a 0.018-inch guidewire is inserted and advanced into the common bile duct. The 22-gauge needle is removed, and coaxial dilators are inserted. **C.** The inner dilator is removed, which permits placement of larger guidewires that negotiate the obstruction into the duodenum. Subsequently, a PTBD catheter is inserted. (From Kadir S: Percutaneous transhepatic cholangiography and biliary drainage. In Kadir S [ed]: *Current Practice of Interventional Radiology*. Philadelphia, BC Decker, 1991, pp 497–510.)

Acalculous Cholecystitis

Acute cholecystitis can develop without gallstones in critically ill or injured patients.²⁹ However, the development of acute acalculous cholecystitis is not limited to surgical or injured patients or even to the intensive care unit. Diabetes, malignant disease, abdominal vasculitis, congestive heart failure, cholesterol embolization, and shock or cardiac arrest have been associated with acute acalculous cholecystitis. Children may also be affected, especially after a viral illness. The pathogenesis of acalculous cholecystitis is thought to include ischemia and reperfusion injury, but opioids, positive pressure ventilation, and total parenteral nutrition have been implicated. The clinical presentation is nonspecific, and significant delays in diagnosis result in a high incidence of gangrene, perforation, abscess, and death.^{30,31} To improve outcome, a high index of suspicion with early imaging, often using multiple studies, is necessary. Ultrasound of the gallbladder is the most accurate diagnostic modality in the critically ill patient, with gallbladder wall thickness of 3.5 mm or greater and pericholecystic fluid being the two most reliable findings.³²

Boland and associates⁹ recommend prophylactic PC for all intensive care unit patients with abdominal sepsis who are not improving and for whom no other etiology can be found. In their series, almost 60% of these patients improved

without further treatment. In the rest, the gallbladder was excluded as the source of sepsis, redirecting the search elsewhere.

Interval cholecystectomy is usually not indicated after acalculous cholecystitis in survivors. If the absence of gallstones is confirmed and the precipitating disorder has been controlled, the cholecystostomy tube can be removed once a track has formed after the patient has recovered.³²

Percutaneous Transhepatic Cholangiography and Drainage

Percutaneous transhepatic cholangiography (PTC) is used to visualize the intrahepatic and extrahepatic ductal system, most commonly to identify the nature and location of biliary obstruction due to stones, tumor, or benign stricture and less commonly to detect a bile leak (Fig. 78-2). If either obstruction or leak is diagnosed, percutaneous biliary drainage, with or without adjunctive stenting, is usually attempted at the same time. Although magnetic resonance cholangiopancreatography (MRCP) also visualizes the ductal system, the combination of PTC and drainage (PTCD) allows a one-step diagnosis and treatment procedure. The majority of patients requiring drainage have malignant disease and eventually have a metallic stent

placed. Percutaneous transhepatic access is also useful for balloon dilation of strictures and biopsy.

TECHNIQUE

For a right-sided fluoroscopic approach, an intercostal point in the midaxillary line is marked in the mid liver with attention paid to the locations of the pleura and colon. The patient should have received antibiotics and conscious sedation. After liberal injection of local anesthetic subcutaneously and down to the hepatic capsule, a 15-cm 22-gauge needle is advanced into the liver in a slightly cephalad direction. The needle obturator is removed and the needle is gradually withdrawn while contrast material is injected gently. Opacification of a bile duct is characterized by an accumulation of contrast material, which persists, unlike vascular opacification, which is transient. Another confirmatory feature is that contrast material in the biliary system drains toward the hilum, in contrast to hepatic arterial or portal venous flow, which is away from the hilum. However, if the biliary tract is occluded, flow of contrast material within it may be very slow. Nondilated ducts are more difficult to access. Next, having confirmed that the opacified bile duct has been accessed peripherally, one should advance a 0.018-inch guidewire into the ductal system as far as the obstruction under fluoroscopic guidance. The authors prefer to use a Neff set (Cook), which is a tapered triaxial access system. Once the Neff dilator is in the duct, its inner two components can be removed, and a 5F Kumpe catheter (Cook) and guidewire can be used to traverse the duct obstruction and to access the duodenum. Once the catheter is in the duodenum, the guidewire can be changed for a stiffer version over which an 8F or 10F internal/external biliary drainage catheter is advanced and the pigtail loop formed in the duodenum. This drainage catheter has multiple side holes allowing drainage above and below the biliary tract obstruction. If traversal of the biliary obstruction is not possible initially, placement of a pigtail drain above the obstruction allows external decompression, and traversal of the obstruction is reattempted after several days.

A left-sided PTC is usually under ultrasound guidance with a subcostal approach to access a segment II or III duct. Once the intraductal needle tip location is confirmed on ultrasound, contrast material is injected, outlining the duct. Again, placement of an internal/external or external biliary drainage catheter is as previously described.

COMPLICATIONS

Important complications include bleeding, infection, and visceral perforation.³³ Significant bleeding, which occurs in 2% to 3%, may be classified on the basis of its source: perihepatic bleed sites (hemothorax, hemoperitoneum, subcapsular hepatic hematoma); gastrointestinal bleeding (hemobilia or melena); and bleeding from the percutaneous biliary drain itself, which is the most common clinical presentation.³⁴ Methods to evaluate and to treat this complication include tractography, angiography, track embolization, arterial embolization, and track site changes.³⁵ Bleeding is more common when the ductal system is accessed centrally than peripherally. Left-sided PTCD is associated with a higher bleeding complication rate than a right-sided approach, presumably because of the greater proximity to larger vessels.³⁶

Significant pain can occur after removal of transhepatic catheters from biliary access tracks, after percutaneous biliary drainage or stenting. The track may be embolized to prevent bile leak and bleeding, reducing the patient's pain.³⁷

Biliary Strictures

MALIGNANT STRICTURE

Bile duct obstruction is commonly caused by pancreaticobiliary malignant neoplasms including gallbladder cancer, cholangiocarcinoma, and pancreatic neoplasms that are frequently unresectable at the time of diagnosis. Inoperable malignant bile duct obstruction can be palliated with surgical bypass, placement of percutaneous biliary drainage catheters, and endoscopic or percutaneous biliary stenting. Indications for biliary drainage/stenting include pruritus, cholangitis, and lowering of bilirubin concentration (<2 mg/dL) before chemotherapy.

Percutaneous biliary drainage is achieved by placement of an internal/external or external plastic pigtail drain after PTC as outlined before. In a review of patients with malignant biliary obstruction who had placement of internal/external biliary drains for lowering of bilirubin concentration, pericatheter leakage occurred in nearly one third of cases, requiring three visits per 100 catheter-days, or approximately one per month.³⁸ Only 31% of patients attained a normal serum bilirubin level by 100 days, and median overall survival was 107 days. Careful patient selection is warranted before biliary drainage for this indication. Maximal biliary drainage, a preprocedure total serum bilirubin concentration of less than 9 mg/dL, and a lower international normalized ratio were factors associated with normalization of the serum bilirubin level in this cohort. In another study from the same institution, it was found that the patient's "quality of life" did not improve after catheter drainage regardless of technical success. Whereas palliation of pruritus was probable, the procedure was less successful in lowering the serum bilirubin concentration to a level that permitted the administration of chemotherapy. The authors concluded that biliary drainage without a clear clinical indication was not supported.³⁹

Internalization of drainage may be achieved with either plastic or metal stents. Compared with plastic stents, metal stents are of larger diameter, have better long-term patency, and are more expensive. The use of metal stents is preferred for patients who are expected to survive for more than 6 months, whereas for patients who are likely to survive for less than 6 months, the use of plastic stents is appropriate. Obstruction in a metal stent may be caused by bile sludge, food debris, or tumor ingrowth. To overcome the last problem, covered metal stents were developed, and these stents are now used in patients with malignant distal biliary obstruction. However, despite their superiority over noncovered stents in terms of improved patency, the incidence of acute cholecystitis and stent migration is higher.⁴⁰

Traditionally, endoscopic stent placement was the preferred method to treat bile duct obstruction because it had higher success and lower complication rates and did not require an external drainage catheter.⁴¹ More recent studies reflect a reversal of this experience, with percutaneous stent placement being more successful and associated with fewer complications than endoscopic procedures, with the main procedural complication, cholangitis, occurring almost five times more commonly with

endoscopically placed stents than with percutaneously placed ones.⁴²⁻⁴⁴ Percutaneous transcholecystic placement of metallic stents is a feasible and effective method to manage malignant obstruction at the lower level of the common bile duct when conventional biliary drainage through transhepatic or endoscopic access is technically difficult.⁴⁵

In primary stenting, the stent is placed at the same session as the initial biliary system access, and this has been found to be effective and safer than a staged procedure with secondary stenting. In a review of 61 patients stented transhepatically for malignant biliary duct obstruction, the rate of major complications was 23% in the primarily stented group and 54% in the secondarily stented group.⁴⁶ Primary stenting is also more cost-effective because of a shorter hospital stay. Reduced morbidity and hospital stay with this technique has been corroborated by other investigators.⁴⁷⁻⁴⁹

A reasonable approach to draining patients with bilobar biliary obstruction may be to insert only a single metallic stent into a liver lobe that constitutes 70% or more of the liver volume, is less involved by tumor than the other lobe, and is supplied by a patent lobar portal vein branch.⁵⁰ Patients with liver lobes of similar size and patent lobar portal vein branches might benefit from bilobar drainage. Drainage of more than two biliary segments is best avoided, except in patients presenting with cholangitis, because of a higher complication rate. The main predictive factor for drainage effectiveness in patients with hilar tumors was a drained liver volume of more than 50%, especially in Bismuth III strictures, which may require bilateral stent placement.⁵¹ Draining an atrophic lobe (<30% of volume) is ineffective and increases the risk of cholangitis.

BENIGN STRICTURE

Percutaneous balloon dilation has become a safe and effective long-term alternative to endoscopic or surgical treatment for benign biliary strictures of various causes.^{52,53} According to the location of the involved duct, the strictures can be categorized as duct anastomotic, biliary-enteric anastomotic, and duct non-anastomotic. The anastomotic strictures represent localized narrowing caused by fibrosis, whereas the nonanastomotic strictures are likely to be associated with ductal ischemia from damage to the bile duct arteries from a variety of causes, including hepatic artery thrombosis. A stricture developing after biliary-enteric anastomosis after low division of the bile duct may be explained by damage to the bile duct artery. Recent experience suggests that anastomotic strictures are more amenable than nonanastomotic strictures to balloon dilation⁵⁴ (Fig. 78-3).

The dilation of the benign stricture is usually performed with a noncompliant balloon (8- to 12-mm diameter) and may be repeated at regular intervals until cholangiography demonstrates free drainage of contrast material to the bowel and no residual stenosis. The internal/external biliary drain is removed after a clinical trial of catheter clamping and a normal cholangiogram.

Percutaneous treatment of benign biliary strictures with extended use of a calibrated internal/external (up to 15F) plastic drain has also had good long-term results.⁵⁵ Endoscopically placed retrievable covered self-expandable metal stents are a recent alternative to progressive plastic stenting for the treatment of benign strictures with the prospect of a higher treatment efficacy and the need for fewer tube changes.⁵⁶

Figure 78-3 Stent placement for benign stricture. This patient developed a biliary-enteric stricture after hepaticojejunostomy for benign pancreatic disease. Repeated balloon dilation of the stricture was unsuccessful. **A.** PTC shows a biliary-enteric stricture (arrow), across which an internal/external drain has been placed. **B** and **C.** Transhepatic deployment of a self-expanding Gianturco Z metallic stent.

Endoscopic intervention is frequently not possible after a Roux-en-Y hepaticojejunostomy or choledochojejunostomy, and percutaneous transhepatic biliary intervention is limited by its inability to access all segments of the biliary tree in a single puncture and carries morbidity as well as discomfort for the patient. A percutaneous transjejunal approach uses an efferent or afferent limb of the Roux-en-Y loop, which is fixed to the peritoneum with the fixation site marked with surgical clips (Hutson loop). Radiologic access is provided to the biliary tree for diagnostic cholangiography, stricture dilation, and intrahepatic stone clearance. Percutaneous catheters need be left in place only for short-term planned repeated interventions (usually in the same admission) for stone disease or for adequate drainage in the case of purulent cholangitis. High success rates and short hospitalizations together with few complications make this option a well-accepted and integral part of managing complex biliary problems.^{57,58}

Common Duct Stone Removal

Up to 18% of people undergoing cholecystectomy for gallstones have common duct stones, which may be treated with exploration (open or laparoscopic) or with endoscopic retrograde cholangiopancreatography (ERCP) before or after cholecystectomy in two stages, usually combined with either sphincterotomy (most common) or sphincteroplasty (papillary dilation) for common bile duct clearance.

The interventionalist may be asked to treat retained bile duct stones through a postoperative drain (T tube or transcystic) placed during cholecystectomy. A less commonly used alternative to these approaches is percutaneous transhepatic removal of bile duct stones when the endoscopic approach fails because of anatomic anomalies or is refused by the patient. Percutaneous transhepatic balloon dilation of the papilla of Vater is performed, followed by pushing of the stones out into the duodenum with a Fogarty balloon catheter. If the stone diameter is larger than 15 mm, basket lithotripsy is recommended before balloon dilation. The overall success rate is greater than 95%, with cholangitis occurring in less than 3% of patients.^{59,60}

Transhepatic cholangioscopy may be necessary for treatment of patients with intrahepatic lithiasis or common bile duct calculi not approachable with retrograde endoscopy, in which direct vision is essential. In patients with very large ductal stones, cholangioscopy combined with percutaneous intracorporeal lithotripsy equipment remains a useful tool.^{61,62}

Percutaneous cholecystolithotomy represents a minimally invasive alternative to cholecystectomy with the disadvantage that gallstones may recur. The procedure consists of three parts: initial PC, track dilation and stone removal, and track evaluation and tube removal. The success rate is as high as 97%, with the main major complication of bile leakage after tube removal reported in less than 10% of patients.^{63,64}

Bile Duct Injury

Bile duct injury (BDI) may occur after gallbladder, pancreas, colonic, and gastric surgery, with laparoscopic cholecystectomy responsible for 80% to 85% of occurrences. Although rare, BDI during laparoscopic cholecystectomy is twice as frequent compared with injury during an open procedure (0.3% open vs. 0.6% laparoscopic), a difference that is not statistically significant. Historically, most BDIs were surgical in nature, with laparoscopic cholecystectomy and liver transplantation

accounting for the majority of cases. Increasingly, ischemic bile duct strictures and bilomas are recognized as a result of hepatic artery chemoembolization and radioembolization treatments for hepatic malignant neoplasms.⁶⁵⁻⁶⁷

Only one third of laparoscopic BDIs are recognized during operation. The majority of patients present initially with non-specific symptoms. Management depends on timing of recognition and the type, extent, and level of the injury. Immediate recognition and repair are associated with improved outcome, and the standard of care after recognition of BDI is referral to a tertiary care hospital that can provide a multidisciplinary approach. Inadequate management may lead to severe complications, with the late clinical course of BDI resulting in chronic liver disease, cirrhosis, and portal hypertension, for which liver transplantation is an option.⁶⁸

BDI may cause bile leakage, abscesses, cholangitis, and secondary biliary cirrhosis due to chronic strictures. The role of interventional radiology in managing patients with BDI is to document the location and nature of the injury, to drain or divert bile, and to promote and provide long-term biliary drainage when appropriate.⁶⁹ Imaging is essential for the evaluation of BDI and subsequent treatment and includes cholescintigraphy, ultrasonography, computed tomography, ERCP, PTCD, and fluoroscopy with a contrast medium injected through a surgically or percutaneously placed biliary drainage catheter.

PTC accurately depicts the location and nature of major BDIs in most patients but may not reliably distinguish injuries at the confluence of the lobar ducts from injuries involving the cephalad 2 cm of the common hepatic duct.⁷⁰ MRCP is replacing PTC as the main diagnostic technique for detecting and localizing bile leaks and has become a reliable and non-invasive way of evaluating the intrahepatic and extrahepatic system.⁷¹⁻⁷³

Depending on the type of injury, management may include endoscopic, percutaneous, and open surgical interventions or a combination of all three options. Percutaneous interventions include drainage of bilomas, abscesses, and obstructed ducts. Additional percutaneous procedures include U-tube placement and balloon dilation and stenting of bile duct strictures. Endoscopic and percutaneous interventional procedures may be performed for definitive treatment in patients with biliary-enteric continuity or as adjuncts to definitive surgical repair. The interventionalist is sometimes challenged to restore biliary-enteric continuity with remarkable ingenuity and innovation.^{74,75}

In a 10-year review of 51 patients with intact biliary-enteric continuity referred for management of BDI, all patients had PTCD followed by balloon dilation and long-term internal/external catheter drainage.⁷⁶ Fifty patients (98%) were drain free at mean follow-up of 76 months, and the success rate of percutaneous management was 58%, without need for subsequent intervention. Percutaneous treatment was more likely to fail in patients who had an internal/external drain for less than 4 months.

Multiple BDI classifications have been developed before and during the laparoscopic era. The Bismuth-Corlette classification was introduced before laparoscopy and is based on the complete section of the common bile duct and the length of the proximal bile duct stump.⁷⁷ Type I is a low injury with a stump length of more than 2 cm. Type II is a middle-level injury with a stump length of less than 2 cm. Type III is a high-level injury without common hepatic duct available but preserved confluence. Type IV involves loss of hepatic confluence with no communication

between right and left ducts. There is no Type V. It is difficult to apply this classification system to laparoscopic BDI as most of the technical factors and mechanisms of injury are different from open surgery.

The Strasberg classification offers a comprehensive classification of laparoscopic BDI.⁷⁸ Injuries are divided into five groups (A to E); the E class is similar to the Bismuth classification, a complex BDI with a complete transection of the duct. Only right and left partial injuries (which account for less than 10% in most series) are not included in this classification. Class A represents a bile leak from the cystic duct or an accessory duct. In both conditions, there is continuity with the common bile duct. Class B is the section of an accessory duct with no continuity with the common bile duct. Class C represents a leak from a bile duct with no continuity with the common bile duct. Class D is a partial section of a bile duct with no complete loss of continuity with the rest of the bile duct system. Class E is a complete transection of the bile duct with subtypes according to the length of the stump (E1-E5) (Strasberg types E1-E4 correspond to Bismuth types I-V).

BDIs are frequently accompanied by vascular injuries, which may worsen the injury and cause liver ischemia.⁷⁹ Right hepatic artery vasculobiliary injury is the most common variant and extends the biliary injury to a higher level than the grossly observed mechanical injury. Vasculobiliary injury results in slow hepatic infarction in about 10% of patients. Repair of the artery is rarely possible and the overall benefit is unclear. Injuries involving the portal vein or common or proper hepatic arteries are much less common but have more serious effects, including rapid infarction of the liver. Routine arteriography is recommended in patients with a biliary injury if early repair is contemplated. Consideration should be given to delaying repair of a biliary injury in patients with occlusion of the right hepatic artery. Patients with injuries to the portal vein or proper or common hepatic artery should be emergently referred to tertiary care centers.

A Strasberg class E5 injury is defined by a complete loss of biliary-enteric continuity and is best treated surgically. Devascularization and loss of bile duct tissue necessitate creation of a Roux-en-Y hepatojejunostomy, a procedure that guarantees well-perfused bile ducts and a low-tension anastomosis (Fig. 78-4). Partial resection of IV and V segments may be necessary to facilitate identification of bile ducts and proper positioning of the jejunal loop. By contrast, the less preferable choledochocolocholedochal or hepatoduodenal anastomoses involve devascularized ducts and the duodenum tends to move caudally, increasing the anastomotic tension.

In a meta-analysis of 31 studies, a total of 99 partial hepatectomies were reported among 1756 (5.6%) patients referred for postcholecystectomy BDI.⁸⁰ Multivariate analysis showed that hepatic arterial and Strasberg E4 and E5 injuries were independent factors associated with partial hepatectomy, and those patients with combined arterial and Strasberg E4 or E5 injury were 43.3 times more likely to undergo partial hepatectomy than were patients without complex injury. Despite the high postoperative morbidity, mortality rates were comparable with those of hepaticojejunostomy.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) is a chronic inflammatory disease characterized by the destruction of medium-sized to large bile ducts and intense concentric fibrosis. Complications

Figure 78-4 Bile duct injury. Right-sided PTC shows a complete occlusion at the duct confluence due to a surgical clip. Traversal of this occlusion and placement of an internal/external drain were not possible, and the patient required a hepaticojejunostomy.

of PSC include bacterial cholangitis, cirrhosis, and cholangiocarcinoma. BDI results from the sustained inflammation and production of inflammatory cytokines. Biliary strictures may cause further damage as a result of bile stasis and recurrent secondary bacterial cholangitis. A retrospective study of 71 patients with PSC showed no additional benefit from stenting after balloon dilation in the treatment of dominant strictures. Stenting was associated with more complications.⁸¹ The only proven curative treatment for PSC is liver transplantation.

Patients with PSC are at risk for development of superimposed cholangiocarcinoma with a 10-year cumulative incidence of approximately 7% to 9%. Cholangiocarcinoma mimics the stricturing process of PSC, and the diagnosis of cholangiocarcinoma in the setting of PSC remains challenging if a mass lesion is not identified by imaging studies. The most definitive evidence of cholangiocarcinoma is a mass lesion with delayed venous phase enhancement on imaging and a positive cytology or biopsy finding.⁸²

Biopsy

Malignant disease of the biliary tract may be a difficult diagnosis to make as radiologic features are nonspecific. Biliary strictures may be directly sampled by brushing, forceps biopsy, fine-needle aspiration, or a combination of these. Cytologic evaluation of brushings obtained endoscopically from the biliary tree is currently the standard of care in most institutions. However, this technique has been plagued by low sensitivity and interpretative difficulties in differentiating reactive from malignant cytologic features. Simply submitting the entire cytology brush for histologic sectioning may increase the sensitivity to 90%.⁸³ The use of fluorescent in situ hybridization technique also increases the sensitivity of cytology.

Alternatively, percutaneous transluminal forceps biopsy is a safe procedure that is easy to perform through a transhepatic biliary drainage tract, in which it is relatively accurate in the diagnosis of malignant biliary obstructions.⁸⁴ In a comparative study, 108 patients underwent forceps biopsy plus cytologic sampling by washing of the forceps device in cytologic solution.⁸⁵ Histologic diagnosis after forceps biopsy was more successful than cytology, with a sensitivity of 78% versus 61% and negative predictive value of 30% versus 19%. Cytology results were never positive when the forceps biopsy finding was negative.

Photodynamic therapy (PDT) is a local, minimally invasive palliative treatment for unresectable cholangiocarcinoma. PDT

uses a photosensitive molecule that accumulates in tumors. Activation of the photosensitizer by a laser introduced endoscopically or percutaneously generates reactive oxygen radicals, leading to selective tumor cell death. Results from two prospective randomized controlled trials comparing PDT after stent insertion with stents alone for patients with unresectable cholangiocarcinoma have shown dramatically prolonged median survival and improved performance status in the PDT group compared with the non-PDT group.^{86,87} The procedures were generally well tolerated and are associated with outcomes as favorable as those of adjuvant and neoadjuvant therapy for cholangiocarcinoma.

Other Malignant Neoplasms of the Bile Ducts

Benign Bile Duct Neoplasms

Most neoplasms that arise from the gallbladder and bile ducts are malignant. Although infrequent, gallbladder and bile duct carcinomas are not rare. Gallbladder carcinoma is the seventh most common malignant neoplasm of the gastrointestinal tract and the most common biliary malignant neoplasm; bile duct carcinoma occurs less often.¹ Familiarity with the imaging characteristics of gallbladder and bile duct neoplasms is important to expedite diagnosis and appropriate treatment of patients, who often present with nonspecific symptoms of right upper quadrant pain, jaundice, and weight loss.

Gallbladder Carcinoma

EPIDEMIOLOGY

Carcinoma of the gallbladder is responsible for at least 3000 deaths per year in the United States.¹ Gallbladder cancer is the sixth most common cancer of the digestive system but accounts for only 3% to 4% of all gastrointestinal cancers. Carcinoma of the gallbladder is two to three times more common in women than in men, and its incidence steadily increases with age, although it varies greatly in different parts of the world.²⁻⁶ More than 90% of patients are older than 50 years; the peak incidence

is 70 to 75 years. Some geographic areas have a high incidence of gallbladder cancer, including South America and India.⁵ Certain groups, such as Israelis, Native Americans, Spanish Americans in the southwest United States, and Eskimos in Alaska, have a significantly higher incidence of gallbladder carcinoma and cholelithiasis than do populations.^{7,8}

ETIOLOGY

Several factors have been associated with an increased risk for development of gallbladder carcinoma. The presence of gallstones is considered to be an important risk factor for gallbladder carcinoma. Of patients with gallbladder carcinoma, 65% to 90% have gallstones, an incidence considerably higher than that for age- and sex-matched control groups.^{6,9} Many gallbladder cancers are unsuspected and found incidentally during surgery for gallstones or on final histologic analysis of the specimen. Diffuse mural calcification, the “porcelain” gallbladder, is another predisposing factor, ranging from 20% to 50% leading to cancer.^{10,11} Other risk factors include the presence of gallbladder adenomas, an anomalous pancreaticobiliary duct junction, and exposure to carcinogenic chemicals.^{6,12,13}

PATHOLOGIC FINDINGS

Most carcinomas of the gallbladder are adenocarcinomas (85%-90%) and can be papillary, tubular, mucinous, or signet cell type. The remainder are anaplastic, squamous cell, or adenosquamous carcinomas.^{14,15} On macroscopic examination, carcinomas of the gallbladder can appear as poorly defined areas of diffuse gallbladder wall thickening (infiltrating), often with a desmoplastic reaction, or as a cauliflower mass (fungating) that grows into the gallbladder lumen. The infiltrating type invades the gallbladder wall and ultimately replaces the lumen with a tumor mass. The papillary form grows into and eventually fills the lumen.¹⁶ Some tumors may show a combination of the infiltrating and fungating patterns. Approximately 60% of carcinomas originate in the fundus, 30% in the body, and 10% in the neck.¹⁷ In some cases, the tumor may diffusely infiltrate the entire gallbladder, making its organ of origin impossible to identify.

The gallbladder has unique anatomic features; the wall consists of a mucosa, lamina propria, smooth muscle layer, perimuscular connective tissue, and serosa without a submucosa. Furthermore, no serosa exists at the attachment to the liver and along the hepatic surface. The connective tissue is continuous with the interlobular connective tissue of the liver.¹⁷ Gallbladder carcinoma is staged surgically by the depth of invasion, extension of disease into adjacent structures, involvement of lymph nodes, and presence of metastases by the American Joint Committee on Cancer TNM staging system.^{2,18}

BOX 79-1 TNM CLASSIFICATION SYSTEM FOR STAGING GALLBLADDER CARCINOMA**PRIMARY TUMOR (T)**

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor invades mucosa or muscle layer
T1a	Tumor invades the mucosa
T1b	Tumor invades the muscle layer
T2	Tumor invades the perimuscular connective tissue; no extension beyond the serosa or into the liver
T3	Tumor perforates the serosa (visceral peritoneum) and/or directly invades the liver and/or one other adjacent organ or structure such as stomach, duodenum, colon, pancreas, omentum, or extrahepatic bile ducts
T4	Tumor invades main portal vein or hepatic artery or invades two or more extrahepatic organs or structures

REGIONAL LYMPH NODES (N)

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastases to nodes along the cystic duct, common bile duct, hepatic artery, and/or portal vein
N2	Metastases to periaortic, pericaval, superior mesenteric artery and/or celiac artery lymph nodes

DISTANT METASTASIS (M)

M0	No distant metastasis
M1	Distant metastasis

STAGE GROUPING

Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage IIIA	T3	N0	M0
Stage IIIB	T1-3	N1	M0
Stage IVA	T4	N0-1	M0
Stage IVB	Any T	N2	M0
	Any T	Any N	M1

(Box 79-1). Invasion of the muscularis mucosa distinguishes T1 from T2 cancers.

CLINICAL FINDINGS

Gallbladder carcinoma most often is manifested with right upper quadrant abdominal pain simulating more common biliary and nonbiliary disorders.¹⁹ Weight loss, jaundice, and an abdominal mass are less common presenting symptoms. Patients may have long-standing symptoms of chronic cholecystitis with a recent change in the quality or frequency of the painful episodes. Other common presentations are similar to either acute cholecystitis or symptoms of biliary malignant disease. Hepatomegaly and ascites suggest liver invasion. Gallbladder carcinoma is occasionally an incidental finding on abdominal imaging studies. Elevated serum levels of α -fetoprotein and carcinoembryonic antigen have been reported in association with gallbladder carcinoma.^{17,20}

RADIOGRAPHIC FINDINGS

Traditional plain oral cholecystography and barium studies of the gastrointestinal tract have a limited role in the imaging of

gallbladder carcinoma. Abdominal radiographs may show calcified gallstones, porcelain gallbladder, or, rarely, punctate calcifications from mucinous carcinomas.²¹ Biliary gas from malignant gallbladder–enteric fistula is another rare finding.²² The gallbladder fails to opacify in at least two thirds of patients with carcinoma of the gallbladder, usually because of cystic duct obstruction.¹⁶ Barium study findings are abnormal in limited cases, showing displacement or direct invasion of the duodenum or anterior limb of the hepatic flexure.

Ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI) are the most valuable imaging modalities for evaluation of patients with gallbladder carcinoma. Patients with right upper quadrant pain should initially be examined with ultrasound. Ultrasound can detect lesions suggestive of gallbladder cancer, such as a wide polyp base and irregular borders. The diagnostic accuracy of ultrasound in gallbladder cancer is more than 80%, but it has limitations in tumor staging.²³ Ultrasound can be useful for differentiating adenomyomatosis from the wall-thickening type of gallbladder cancer by detecting intramural cystic spaces or echogenic foci within the wall.^{24–28} Doppler imaging can be useful for differentiating polyp from tumefactive sludge by demonstrating blood flow to the polypoid tumors (Fig. 79-1). Endoscopic ultrasound is useful in depicting the depth of tumor invasion and for characterizing polypoid lesions.^{26,27} CT is superior to ultrasound in assessing lymphadenopathy and spread of the disease into the liver, porta hepatis, or adjacent structures and is useful in predicting which patients will benefit from surgical therapy (Fig. 79-2).^{28,29} Although MRI can be useful in assessing the cause of focal or diffuse mural thickening and helps differentiate gallbladder cancer from adenomyomatosis and chronic cholecystitis,^{30,31} magnetic resonance cholangiopancreatography (MRCP) provides more detailed information than ultrasound or CT about biliary involvement of the tumor. In addition, adding diffusion-weighted imaging to the standard MRI protocol may improve sensitivity for distinguishing gallbladder cancers from benign gallbladder diseases with wall thickening (Fig. 79-3).^{32–34} Although direct cholangiographic techniques such as endoscopic retrograde cholangiopancreatography (ERCP) and percutaneous transhepatic cholangiography are of little value in detecting the presence of gallbladder carcinoma, they are helpful in planning the surgical procedure because they can show tumor growth into adjacent intrahepatic ducts or into the common bile duct.⁶ The cholangiographic differential diagnosis includes cholangiocarcinoma, metastases, Mirizzi syndrome, and pancreatic carcinoma.

Radiologic Evaluation of the Primary Tumor

Gallbladder carcinomas have three major histologic and imaging presentations: focal or diffuse thickening or irregularity of the gallbladder wall; polypoid mass originating in the gallbladder wall and projecting into the lumen; and most commonly, a mass obscuring or replacing the gallbladder, often invading the adjacent liver.^{25,28,30}

Carcinoma Manifesting as Mural Thickening. Focal or diffuse thickening of the gallbladder wall is the least common presentation of gallbladder carcinoma and is the most difficult to diagnose, particularly in the early stages. Gallbladder carcinoma may cause mild to marked mural thickening in a focal or diffuse pattern. This thickening is best appreciated sonographically; the gallbladder wall is normally 3 mm or less in

Figure 79-1 Ultrasound and Color Doppler imaging findings of polypoid gallbladder carcinoma. **A.** Subcostal sonogram shows a polypoid mass with a homogeneous tissue texture that is fixed to the gallbladder wall at its base. **B.** Color Doppler imaging shows blood flow signals in the polypoid mass. **C.** Precontrast axial CT scan demonstrates a polypoid mass (arrow) showing hyperattenuation to surrounding bile of the gallbladder. **D.** Axial CT scan demonstrates a homogeneously enhancing polypoid gallbladder carcinoma (arrow) with an enhancing vessel (open arrow). **E.** Photograph of the opened resected specimen shows the cauliflower-like intraluminal growth of a papillary adenocarcinoma.

Figure 79-2 Polypoid gallbladder carcinoma with nodal metastasis. CT scan demonstrates a polypoid gallbladder carcinoma (black arrow) and low-density portocaval and para-aortic lymph nodes containing metastases (white arrows).

thickness.³⁵ Carcinomas confined to the gallbladder mucosa may be manifested as flat or slightly raised lesions with mucosal irregularity that are difficult to appreciate sonographically. In one sonographic series, half the patients with these early carcinomas had no protruding lesions, and fewer than one third were identified preoperatively.³⁶ More advanced gallbladder carcinomas can cause marked mural thickening, often with

irregular and mixed echogenicity (Fig. 79-4). The gallbladder may be contracted, normal sized, or distended, and gallstones are usually present. When cancer occurs in the neck portion of the gallbladder, identification of cystic duct involvement by the tumor on imaging merits consideration of focal bile duct resection to achieve a negative resection margin (see Fig. 79-4).

Four factors interfere with the sonographic recognition of carcinoma as the cause of gallbladder wall thickening:

1. Changes of early gallbladder carcinoma may be only subtle mucosal irregularity or mural thickening.
2. Gallbladder wall thickening is a nonspecific finding that can also be caused by acute or chronic cholecystitis, hyperalimentation, portal hypertension, adenomyomatosis, inadequate gallbladder distention, hypoalbuminemia, hepatitis, hepatic failure, cardiac failure, or renal failure. The echo architecture of the wall can sometimes help narrow the differential diagnosis.^{37,38} In acute cholecystitis, the wall often has irregular, discontinuous hypoechoic and echogenic bands. Chronic cholecystitis often results in a uniformly echodense band surrounding the mucosa, and hypoproteinemia may have a hypoechoic central band. Pronounced wall thickening (>1.0 cm) demonstrated by ultrasonography with associated mucosal irregularity or marked asymmetry should raise concerns for malignant disease or complicated cholecystitis.^{24,25}
3. Chronic cholecystitis is often present in patients with gallbladder carcinoma.
4. Shadowing stones or gallbladder wall calcification may obscure the carcinoma.

Figure 79-3 Gallbladder cancer showing enhancement on MRI and a high signal intensity on diffusion-weighted imaging. **A.** Fat-suppressed T2-weighted MR image shows an asymmetrically thickened gallbladder wall with hypointensity (arrows) compared with edematous surrounding wall. **B.** Postgadolinium fat-suppressed T1-weighted image reveals slightly heterogeneous enhancement of the thickened gallbladder wall (arrows). **C.** High b value ($b = 1000$) diffusion-weighted imaging demonstrates a high signal intensity of the tumor (arrows) involving the fundus of the gallbladder. **D.** MRCP demonstrates a luminal narrowing of the fundus (arrows) caused by the tumor and a normal appearance of the bile duct.

Figure 79-4 Gallbladder cancer manifesting as mural thickening at the neck portion. **A.** Intercostal sonogram shows a marked thickening of gallbladder wall (arrows) in the neck portion. **B.** Coronal reformatted CT image shows an enhancing, thick gallbladder wall (arrows) with lumen narrowing. **C.** Photograph of the opened resected specimen shows an irregular wall thickening of the neck portion of the gallbladder as well as a patent cystic duct (arrows).

Although CT is inferior to ultrasound for evaluating the gallbladder wall for mucosal irregularity, mural thickening, and cholelithiasis, it is superior for evaluating the thickness of portions of the gallbladder wall that are obscured by interposed gallstones or mural calcifications on ultrasound.^{28,37,39} On contrast-enhanced CT, thick (>2.5 mm) and strong enhancement of the inner wall and irregular contour of the affected wall are significant predictors for a malignant cause of gallbladder wall thickening (Fig. 79-5).^{29,40} When focal or irregular thickening of the gallbladder wall is encountered on CT, the images should be carefully inspected for bile duct dilation, local invasion, metastasis, or adenopathy.^{29,40} Multiplanar reformatted images of multidetector CT (MDCT) scans could be valuable for demonstrating extent of gallbladder cancers as well as relationship with adjacent organs, similar to biliary malignant tumors⁴¹⁻⁴⁴ (see Fig. 79-4). Studies have also demonstrated that diffusion-weighted MRI could contribute to the improvement of the diagnostic capability for gallbladder wall thickening or polypoid lesions by demonstrating high signal intensity on high b value diffusion-weighted imaging and a lower apparent diffusion coefficient value of gallbladder cancers than that of benign gallbladder diseases (see Fig. 79-3).^{32,33}

Carcinoma Manifesting as a Polypoid Mass. About one fourth of gallbladder carcinomas are manifested as a polypoid mass projecting into the gallbladder lumen. Identification of these neoplasms is particularly important because they are well differentiated and are more likely to be confined to the gallbladder mucosa or muscularis when discovered.^{36,45}

Polypoid carcinomas on ultrasound usually have a homogeneous tissue texture, are fixed to the gallbladder wall at their base, and do not cast an acoustic shadow^{25,27} (Fig. 79-6; see also Fig. 79-1). Most are broad based with smooth borders, although occasional tumors have a narrow stalk or villous fronds. The

polyp may be hyperechoic, hypoechoic, or isoechoic relative to the liver. Gallstones are usually present, and the gallbladder is either normal sized or expanded by the mass. A small polypoid carcinoma can be indistinguishable from a cholesterol polyp, adenoma, or adherent stone. Most benign polyps are small, measuring less than 1 cm.^{26,27,37} If a gallbladder polyp is larger than 1 cm in diameter and is not clearly benign, cholecystectomy should be considered.³⁶ Tumefactive sludge or blood clot can simulate a polypoid carcinoma.²⁵ Positional maneuvers usually differentiate these entities; clots and sludge move, albeit slowly, whereas cancers do not. Color Doppler imaging is also valuable for differentiating a polypoid tumor from tumefactive sludge by demonstrating vascular flow within tumors²⁸ (see Fig. 79-1). When polypoid carcinomas are sufficiently large, they are manifested as soft tissue masses that are denser than surrounding bile on CT scans or show a hypointensity to surrounding bile on T2-weighted MR imaging (see Fig. 79-6).³⁰ The polypoid cancer usually enhances homogeneously after administration of contrast medium, and the adjacent gallbladder wall may be thickened (see Figs. 79-1 and 79-6). Necrosis or calcification is uncommon.

Carcinoma Manifesting as a Gallbladder Fossa Mass. A large mass obscuring or replacing the gallbladder is the most common (42%-70%) presentation of gallbladder carcinoma.^{28,30} On sonographic examination, the mass is often complex, with regions of necrosis, and small amounts of pericholecystic fluid are often present. Gallstones are commonly seen within the ill-defined mass, which typically invades hepatic parenchyma.

On CT scans, infiltrating carcinomas that replace the gallbladder often show irregular contrast enhancement with scattered regions of internal necrosis (Fig. 79-7).³⁰ Unless the associated gallstones are densely calcified, they may be difficult to identify. Invasion of the liver or hepatoduodenal ligament,

Figure 79-5 Gallbladder carcinoma: mural thickening. **A.** Subcostal sonogram shows a markedly thickened, inhomogeneous gallbladder wall (arrows). **B.** CT shows an enhancing, thick gallbladder wall (arrows) with lumen narrowing. **C.** Photograph of the opened resected specimen shows a thickening of the gallbladder wall (arrows).

Figure 79-6 Polypoid gallbladder carcinoma having a wide base with a gallbladder wall. **A.** Sonogram shows a large homogeneous, hyperechoic polypoid gallbladder carcinoma (arrow) relative to surrounding bile. The mass was immobile with changes in the patient's position. **B.** Precontrast axial CT scan demonstrates a hyperattenuated soft tissue density polypoid tumor (arrow) in the gallbladder. **C.** Postcontrast axial CT scan demonstrates a homogeneously enhancing polypoid gallbladder carcinoma that is broad based with smooth border (arrow). **D.** Postcontrast T1-weighted MR image also demonstrates a polypoid mass showing hyperenhancement (arrow). **E.** Coronal T2-weighted image demonstrates a hypointense polypoid tumor (arrow) in the gallbladder. **F.** Photograph of the opened resected specimen shows a polypoid gallbladder cancer (arrow).

Figure 79-7 Gallbladder carcinoma manifesting as a gallbladder fossa mass. **A.** CT scan demonstrates an irregular hypodense mass replacing the gallbladder extending into the hepatic parenchyma (arrows). Note dilated common duct with wall thickening, suggesting spreading to the extrahepatic bile duct. **B.** Photograph of the resected specimen shows a large mass replacing the gallbladder (arrows).

satellite lesions, hepatic or nodal metastases, and bile duct dilation are also common.

MRI findings in gallbladder carcinoma are similar to those reported with CT. MRI demonstrates prolongation of the T1 and T2 relaxation time in gallbladder carcinoma. These lesions are heterogeneously hyperintense on T2-weighted images and hypointense on T1-weighted images compared with liver parenchyma.⁴⁶ Ill-defined early enhancement is a typical appearance of gallbladder carcinoma on dynamic gadolinium-enhanced MRI²⁹ (Fig. 79-8). MRI with MRCP offers the potential of evaluating parenchymal, vascular, biliary, and nodal involvement with a single noninvasive examination (Fig. 79-9).³⁰ On the basis of MRI alone, it may be difficult to distinguish carcinoma of the gallbladder from inflammatory and metastatic disease.

Differential Diagnosis

The differential diagnosis of infiltrating gallbladder carcinomas includes more common inflammatory and noninflammatory causes of wall thickening. These include heart failure, cirrhosis, hepatitis, renal failure, complicated cholecystitis, xanthogranulomatous cholecystitis, and adenomyomatosis.^{28,38,39} Clinically and radiologically, gallbladder carcinoma can be difficult to differentiate from cholecystitis with pericholecystic fluid and abscess. A increased attenuation intrahepatic halo surrounding the gallbladder wall on contrast-enhanced CT scans or MRI is fairly specific for complicated cholecystitis.^{46,47,48} Gallbladder carcinoma should be suspected when there are features of a focal mass, lymphadenopathy, hepatic metastases, and biliary obstruction at the level of the porta hepatis. Diffuse gallbladder wall thickening and streaky densities in the pericholecystic fat are seen with both inflammation and carcinoma.⁴⁰ Xanthogranulomatous cholecystitis is a pseudotumoral inflammatory
